#### 8041AH/8041AH-2/8641A/8741A UNIVERSAL PERIPHERAL INTERFACE 8-BIT MICROCOMPUTER

8061AH/8041AH-2/8641A/8744A

- 8041AH-2: 12 MHz 8041AH: 8 MHz
- 8-Bit CPU plus ROM, RAM, I/O, Timer and Clock in a Single Package
- One 8-Bit Status and Two Data
   Registers for Asynchronous Slave-to-Master Interface
- DMA, Interrupt, or Polled Operation Supported
- 1024 x 8 ROM/EPROM, 64 x 8 RAM, 8-Bit Timer/Counter, 18 Programmable I/O Pins

- Fully Compatible with MCS-48<sup>TM</sup>, MCS-80<sup>TM</sup>, MCS-85<sup>TM</sup>, and iAPX-86,88 Microprocessor Families
- Interchangeable ROM and EPROM Versions
- Expandable I/O
- RAM Power-Down Capability
- Over 90 Instructions: 70% Single Byte
- Single 5V Supply

The Intel® 8041AH/8741A is a general-purpose, programmable interface device designed for use with a variety of 8-bit microprocessor systems. It contains a low cost microcomputer with program memory, data memory, 8-bit CPU, I/O ports, timer/counter, and clock in a single 40-pin package. Interface registers are included to enable the UPI device to function as a peripheral controller in MCS-48™, MCS-80™, iAPX-85™, iAPX-86, iAPX-88, and other 8- or 16-bit systems.

The UPI-41A<sup>™</sup> has 1K words of program memory and 64 words of data memory on-chip. To allow full user flexibility the program memory is available as ROM in the 8041AH version or as UV-erasable EPROM in the 8741A version. The 8741A and the 8041AH are fully pin compatible for easy transition from prototype to production level designs. The 8741A is a one-time programmable (at the factory) 8741A which can be ordered as the first 25 pieces of a new 8041AH order. The substitution of 8641As for 8041AHs allows for very fast turnaround for initial code verification and evaluation results.

The device has two 8-bit, TTL-compatible I/O ports and two test inputs. Individual port lines can function as either inputs or outputs under software control. I/O can be expanded with the 8243 device which is directly compatible and has 16 I/O lines. An 8-bit programmable timer/counter is included in the UPI device for generating timing sequences or counting external inputs. Additional UPI features include: single 5V supply, low power standby mode (in the 8041AH), single-step mode for debug and dual working register banks.

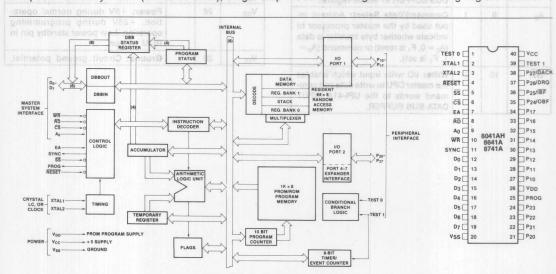

Figure 1. Block Diagram

Figure 2. Pin Configuration

#### Table 1. Pin Description

Symbol	Pin No.	Туре	Name and Function
TEST 0, TEST 1	1 39	86	Test Inputs: Input pins which can be directly tested using conditional branch instructions.
107 C		bne	Frequency Reference: TEST 1 (T <sub>1</sub> ) also functions as the event timer input (under software control). TEST 0 (T <sub>0</sub> ) is used during PROM programming and verification in the 8741A.
XTAL 1, XTAL 2	2 3	S %	Inputs: Inputs for a crystal, LC or an external timing signal to determine the internal oscillator frequency.
RESET	4	1	Reset: Input used to reset status flip- flops and to set the program counter to zero.
	data data	OF US	RESET is also used during PROM programming and verification.
SS	5	X9Ai	Single Step: Single step input used in the 8741A in conjunction with the SYNC output to step the program through each instruction.
M in <mark>ZD</mark> otype to ordere	ong i	non i	Chip Select: Chip select input used to select one UPI-41A microcomputer out of several connected to a common data bus.
EA notion	ut de	nes c	External Access: External access input which allows emulation, testing and PROM/ROM verification. This pin should be tied low if unused.
evice <mark>dR</mark> o V supply banks.	gle 5	nie : el	Read: I/O read input which enables the master CPU to read data and status words from the OUTPUT DATA BUS BUFFER or status register.
A <sub>0</sub>	9	1 0	Command/Data Select: Address input used by the master processor to indicate whether byte transfer is data $(A_0 = 0, F_1 \text{ is reset})$ or command $(A_0 = 1, F_1 \text{ is set})$ .
WR E SP DAGUES E SE SEGUES E SE SEGUES E SE	10	1 D 10 1 D 28 1 D 28 2 D 28	Write: I/O write input which enables the master CPU to write data and com- mand words to the UPI-41A INPUT DATA BUS BUFFER.

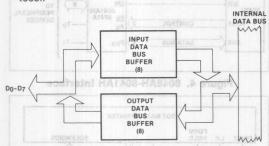

Symbol	Pin No.	Туре	Name and Function
SYNC	CONTROL OF SERVICE BOOK AND ADDRESS.		Output Clock: Output signal which occurs once per UPI-41A instruction cycle. SYNC can be used as a strobe for external circuitry; it is also used to synchronize single step operation.
D <sub>0</sub> -D <sub>7</sub> (BUS)	12-19	0 0	Data Bus: Three-state, bidirectiona DATA BUS BUFFER lines used to interface the UPI-41A microcompute to an 8-bit master system data bus.
P <sub>10</sub> -P <sub>17</sub>	27-34	1/0	Port 1: 8-bit, PORT 1 quasi-bidirectional I/O lines.
P20-P27	ontain no ci s a p ms. ms. ram rabl	s. It or tion a syste prog is avi	Port 2: 8-bit, PORT 2 quasi-bidirectional I/O lines. The lower 4 bits (P <sub>20</sub> -P <sub>23</sub> ) interface directly to the 8243 I/O expander device and contain address and data information during PORT 4-7 access. The upper 4 bits (P <sub>24</sub> -P <sub>27</sub> ) can be programmed to provide interrupt Request and DMA Handshake capability. Software control can configure P <sub>24</sub> as Output Buffer Full (IOBF) interrupt, P <sub>25</sub> as Input Buffer Full (IBF) interrupt, P <sub>26</sub> as DMA Request (DRQ), and P <sub>27</sub> as DMA ACKnowledge (DACK).
PROG	25	1/0	<b>Program:</b> Multifunction pin used as the program pulse input during PROM programming.
/O ports ontrot. I/O I progra external		softwa ss. Ar	During I/O expander access the PROG pin acts as an address/data strobe to the 8243. This pin should be tied high if unused.
Vcc	40	e 804	Power: +5V main power supply pin.
V <sub>DD</sub>	26		Power: +5V during normal opera- tion. +25V during programming operation. Low power standby pin in ROM version.
V <sub>SS</sub>	20	AHOOMA - 7	Ground: Circuit ground potential

Figure 1. Block Diagram

## UPI-41A™ FEATURES AND ENHANCEMENTS

 Two Data Bus Buffers, one for input and one for output. This allows a much cleaner Master/Slave protocol.

2. 8 Bits of Status

ST<sub>4</sub>-ST<sub>7</sub> are user definable status bits. These bits are defined by the "MOV STS, A" single byte, single cycle instruction. Bits 4-7 of the accumulator are moved to bits 4-7 of the status register. Bits 0-3 of the status register are not affected.

 RD and WR are edge triggered. IBF, OBF, F<sub>1</sub> and INT change internally after the trailing edge of RD or WR.

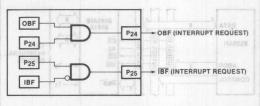

During the time that the host CPU is reading the status register, the 8041AH is prevented from updating this register or is 'locked out.'

 P<sub>24</sub> and P<sub>25</sub> are port pins or Buffer Flag pins which can be used to interrupt a master processor. These pins default to port pins on Reset.

If the "EN FLAGS" instruction has been executed,  $P_{24}$  becomes the OBF (Output Buffer Full) pin. A "1" written to  $P_{24}$  enables the OBF pin (the pin outputs the OBF Status Bit). A "0" written to  $P_{24}$  disables the OBF pin (the pin remains low). This pin can be used to indicate that valid data is available from the UPI-41A (in Output Data Bus Buffer).

If "EN FLAGS" has been executed,  $P_{25}$  becomes the  $\overline{\text{IBF}}$  (Input Buffer Full) pin. A "1" written to  $P_{25}$  enables the  $\overline{\text{IBF}}$  pin (the pin outputs the inverse of the IBF Status Bit). A "0" written to  $P_{25}$  disables the  $\overline{\text{IBF}}$ 

pin (the pin remains low). This pin can be used to indicate that the UPI-41A is ready for data.

DATA BUS BUFFER INTERRUPT CAPABILITY

 P<sub>26</sub> and P<sub>27</sub> are port pins or DMA handshake pins for use with a DMA controller. These pins default to port pins on Reset.

If the "EN DMA" instruction has been executed, P<sub>26</sub> becomes the DRQ (DMA ReQuest) pin. A "1" written to P<sub>26</sub> causes a DMA request (DRQ is activated). DRQ is deactivated by DACK·RD, DACK·WR, or execution of the "EN DMA" instruction.

If "EN DMA" has been executed,  $P_{27}$  becomes the DACK (DMA ACKnowledge) pin. This pin acts as a chip select input for the Data Bus Buffer registers during DMA transfers.

#### **8041AH ENHANCEMENTS OVER 8041A**

- The RESET input on the 8041AH was changed to include a 2 stage synchronizer to support reliable reset operation for 12 MHz operation.
- As noted in the status register description, during the time that the host CPU is reading the status register, the 8041AH is prevented from updating or is 'locked out.'
- When EA is enabled on the 8041A, the program counter is placed on Port 1 and the lower two bits of Port 2. On the 8041AH, this information is multiplexed with PORT DATA (see port timing diagrams at end of this data sheet).
- The 8041AH additionally supports single step mode as described in the pin description section.

#### PROGRAMMING, VERIFYING, AND **ERASING THE 8741A EPROM**

#### Programming Verification

In brief, the programming process consists of: activating the program mode, applying an address, latching the address, applying data, and applying a programming pulse. Each word is programmed completely before moving on to the next and is followed by a verification step. The following is a list of the pins used for programming and a description of their functions:

res Pin Idealor	clude a 2 stage synchronizenoitone
XTAL 1	Clock Input (1 to 6MHz)
Reset	Initialization and Address Latching
Test 0	Selection of Program or Verify Mode
EA	Activation of Program/Verify Modes
BUS	Address and Data Input
TRO9 driw be	Data Output During Verify
818P20-1	Address Input salmit mod eas) ATAO
V <sub>DD</sub>	Programming Power Supply (1994)
PROG	Program Pulse Input

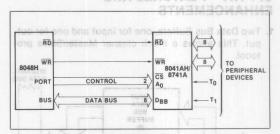

Figure 4. 8048AH-8041AH Interface

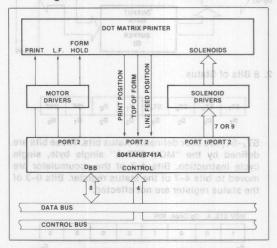

Figure 6. 8041AH Matrix Printer Interface

#### WARNING:

An attempt to program a missocketed 8741A will result in severe damage to the part. An indication of a properly socketed part is the appearance of the SYNC clock output. The lack of this clock may be used to disable the programmer.

#### The Program/Verify sequence is:

- 1.  $A_0 = 0V$ ,  $\overline{CS} = 5V$ , EA = 5V,  $\overline{RESET} = 0V$ ,  $\overline{TESTO} = 5V$ , V<sub>DD</sub> = 5V, clock applied or internal oscillator operating, BUS and PROG floating.
- Insert 8741A in programming socket
- 3. TEST 0 = 0v (select program mode)
- EA = 23V (activate program model)<sup>1</sup>
- 5. Address applied to BUS and P20-1 80 on a semoned a 9
- RESET = 5v (latch address) 6. Data applied to BUS<sup>2</sup>
- 8. V<sub>DD</sub> = 25v (programming power)<sup>2</sup>
- PROG = 0v followered by one 50ms pulse to 23V<sup>2</sup>
- 10, VDD = 5v as belugaxa need and "20AJR M3" H
- 11. TEST 0 = 5v (verify mode) | III | nettue jugar | Hel

- and of opening nonsimple groups with a strong the strong s
- tion of the device at these or any other covor of the residence.
- 14. RESET = 0v and repeat from step 5 and m betsolbin scort
- 15. Programmer should be at conditions of step 1 when 8741A is removed from socket.

#### NOTE:

- 1. When verifying ROM, EA = 12V.
- 2. Not used in verify ROM procedure.

#### **8741A Erasure Characteristics**

The erasure characteristics of the 8741A are such that erasure begins to occur when exposed to light with wavelengths shorter than approximately 4000 Angstroms (Å). It should be noted that sunlight and certain types of fluorescent lamps have wavelengths in the 3000-4000Å range. Data show that constant exposure to complete the typical strong level fluorescent lighting could grase the typical

8741A in approximately 3 years while it would take approximately one week to cause erasure when exposed to direct sunlight. If the 8741A is to be exposed to these types of lighting conditions for extended periods of time, opaque labels are available from Intel which should be placed over the 8741A window to prevent unintentional erasure.

AUSULUIE MAAIMUM HAIINUD

The recommended erasure procedure for the 8741A is exposure to shortwave ultraviolet light which has a wavelength of 2537Å. The integrated dose (i.e., UV intensity × exposure time) for erasure should be a minimum of 15 w-sec/cm². The erasure time with this dosage is approximately 15 to 20 minutes using an ultraviolet lamp with a 12,000  $\mu$ W/cm² power rating. The 8741A should be placed within one inch of the lamp tubes during erasure. Some lamps have a filter on their tubes which should be removed before erasure.

#### **ABSOLUTE MAXIMUM RATINGS\***

\*NOTICE: Stresses above those listed under "Absolute Maximum Ratings" may cause permanent damage to the device. This is a stress rating only and functional operation of the device at these or any other conditions above those indicated in the operational sections of this specification is not implied. Exposure to absolute maximum rating conditions for extended periods may affect device reliability.

# 8042/8742 UNIVERSAL PERIPHERAL INTERFACE 8-BIT MICROCOMPUTER

- 8042/8742: 12 MHz
- Pin, Software and Architecturally Compatible with 8041A/8741A/8041AH
- 8-Bit CPU plus ROM, RAM, I/O, Timer and Clock in a Single Package
- 2048 × 8 ROM/EPROM, 128 × 8 RAM, 8-Bit Timer/Counter, 18 Programmable I/O Pins
- One 8-Bit Status and Two Data Registers for Asynchronous Slave-to-Master Interface
- DMA, Interrupt, or Polled Operation Supported

- Fully Compatible with MCS-48<sup>™</sup>, MCS-51<sup>™</sup>, MCS-80<sup>™</sup>, MCS-85<sup>™</sup>, and iAPX-86. 88 Microprocessor Families
- Interchangeable ROM and EPROM Versions
- Expandable I/O
- RAM Power-Down Capability Tuo Tugali
- Over 90 Instructions: 70% Single Byte
- Single 5V Supply

The Intel 8042/8742 is a general-purpose Universal Peripheral Interface that allows the designer to grow his own customized solution for peripheral device control. It contains a low-cost microcomputer with 2K of program memory, 128 bytes of data memory, 8-bit CPU, I/O ports, 8-bit timer/counter, and clock generator in a single 40-pin package. Interface registers are included to enable the UPI device to function as a peripheral controller in the MCS-48<sup>TM</sup>, MCS-80<sup>TM</sup>, MCS-80<sup>TM</sup>, MCS-85<sup>TM</sup>, iAPX-88, iAPX-86 and other 8-, 16-bit systems.

The 8042/8742 is software, pin, and architecturally compatible with the 8041AH, 8741A. The 8042/8742 doubles the onchip memory space to allow for additional features and performance to be incorporated in upgraded 8041AH/8741A designs. For new designs, the additional memory and performance of the 8042/8742 extends the UPI concept to more complex motor control tasks, 80-column printers and process control applications as examples.

To allow full user flexibility, the program memory is available as ROM in the 8042 version or as UV-erasable EPROM in the 8742 version. The 8742 and the 8042 are fully pin compatible for easy transition from prototype to production level designs. The 8642 is a one-time programmable (at the factory) 8742 which can be ordered as the first 25 pieces of a new 8042 order. The substitution of 8642's for 8042's allows for very fast turnaround for initial code verification and evaluation results.

The device has two 8-bit, TTL compatible I/O ports and two test inputs. Individual port lines can function as either inputs or outputs under software control. I/O can be expanded with the 8243 device which is directly compatible and has 16 I/O lines. An 8-bit programmable timer/counter is included in the UPI device for generating timing sequences or counting external inputs. Additional UPI features include: single 5V supply, low power standby mode (in the 8042), single-step mode for debug, and dual working register banks.

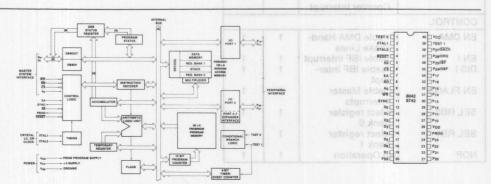

Figure 1. Block Diagram

Figure 2. Pin Configuration

#### of beau ed rep nig sidt (wol anisme) nigTable 1. Pin Description

Symbol	Pin No.	Туре	Name and Function
TEST 0, TEST 1	1 39	TWN RSC	Test Inputs: Input pins which can be directly tested using conditional branch instructions.
TEQUEST		BF (INTE	Frequency Reference: TEST 1 (T <sub>1</sub> ) also functions as the event timer input (under software control). TEST 0 (T <sub>0</sub> ) is used during PROM programming and verification in the 8742.
XTAL 1, XTAL 2	2	I	Inputs: Inputs for a crystal, LC or an external timing signal to determine the internal oscillator frequency.
RESET	4	1	Reset: Input used to reset status flip- flops and to set the program counter to zero.
	Ishak	anan A	RESET is also used during PROM programming and verification.
SS OF H	5	e gins	Single Step: Single step input used in conjunction with the SYNC output to step the program through each instruction.
CS IW People of the contion	etival		Chip Select: Chip select input used to select one UPI microcomputer out of several connected to a common data bus.
EA mos the ote as a		I id, P <sub>2</sub> i This	External Access: External access input which allows emulation, testing and PROM/ROM verification. This pin should be tied low if unused.
RD	8	ı	Read: I/O read input which enables the master CPU to read data and status words from the OUTPUT DATA BUS BUFFER or status register.
Ao	9	HOAN	Command/Data Select: Address input used by the master processor to indicate whether byte transfer is data $(A_0 = 0, F1 \text{ is reset})$ or command $(A_0 = 1, F1 \text{ is set})$ .
WR	10	1	Write: I/O write input which enables the master CPU to write data and command words to the UPI INPUT DATA BUS BUFFER.

Symbol	Pin No.	Туре	Name and Function
AMABYMI BUB AYAQ	8/ <b>11</b> (8)	MO	Output Clock: Output signal which occurs once per UPI-42 instruction cycle. SYNC can be used as a strobe for external circuitry; it is also used to synchronize single step operation.
D <sub>0</sub> -D <sub>7</sub> (BUS)	12-19	I/O	Data Bus: Three-state, bidirectional DATA BUS BUFFER lines used to interface the UPI-42 microcomputer to an 8-bit master system data bus.
P <sub>10</sub> -P <sub>17</sub>	27-34	1/0	Port 1: 8-bit, PORT 1 quasi-bidirectional I/O lines.
P20-P27	Thes		Port 2: 8-bit, PORT 2 quasi-bidirectional I/O lines. The lower 4 bits (P <sub>20</sub> -P <sub>23</sub> ) interface directly to the 8243 I/O expander device and contain address and data information during PORT 4-7 access. The upper 4 bits (P <sub>24</sub> -P <sub>27</sub> ) can be programmed to provide interrupt Request and DMA Handshake capability. Software control can configure P <sub>24</sub> as Output Buffer Full (OBF) interrupt, P <sub>25</sub> as Input Buffer Full (IBF) interrupt, P <sub>26</sub> as DMA Request (DRQ), and P <sub>27</sub> as DMA ACKnowledge (DACK).
PROG	25	1/0	Program: Multifunction pin used as the program pulse input during PROM programming.
00	0	0	During I/O expander access the PROG pin acts as an address/data strobe to the 8243. This pin should be tied high if unused.
Vcc	40	BF, O	Power: +5V main power supply pin.
V <sub>DD</sub> 10 C	26	0 edg	Power: +5V during normal opera- tion. +21V during programming operation. Low power standby pin in ROM version.
V <sub>SS</sub>	20		Ground: Circuit ground potential

 The RESET input on the 8642/8742 includes a 2-stage synchronizer to support reliable reset operation for 12 MHz operation.

When EA is enabled on the 8042/8742, the program counter is placed on Port 1 and the lower three bits of Port 2 (MSB = P<sub>22</sub>, LSB = P<sub>10</sub>). On the 8042/8742 this information is multiplexed with PORT DATA (see port timing diagrams at end of this data sheet).

8. The 8042/8742 supports single step mode as described to the ole descriptor service.

can be used to interrupt a master processor. These pins default to port pins on Resel.

If the "EN FLAGS" instruction has been executed, F24 becomes the OBF (Output Buffer Full) pin. A "1" written to P24 enables the OBF pin (the pin outputs the OBF pin (the pin outputs bit) A "0" written to P24 disables the OBF pin (the pin remains low). This pin can be used to meticate that valid data is available from the UP4 41A (in Output Data Bus Buffer).

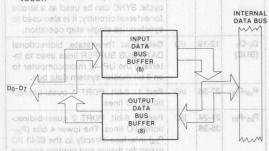

If "EN FLAGS" has been executed, P25 becomes the IBF (Input Buffer Full) pin. A "f" written to P25

#### **UPI-42 FEATURES**

Two Data Bus Buffers, one for input and one for output. This allows a much cleaner Master/Slave protocol.

 Section 2007

2. 8 Bits of Status amoini slub bas

ST<sub>4</sub>-ST<sub>7</sub> are user definable status bits. These bits are defined by the "MOV STS, A" single byte, single cycle instruction. Bits 4-7 of the accumulator are moved to bits 4-7 of the status register. Bits 0-3 of the status register are not affected.

 RD and WR are edge triggered. IBF, OBF, F₁ and INT change internally after the trailing edge of RD or WR.

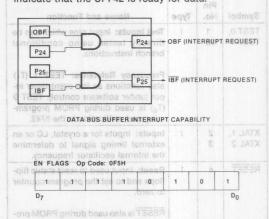

During the time that the host CPU is reading the status register, the 8042/8742 is prevented from updating this register or is 'locked out.'

 P<sub>24</sub> and P<sub>25</sub> are port pins or Buffer Flag pins which can be used to interrupt a master processor. These pins default to port pins on Reset.

If the "EN FLAGS" instruction has been executed,  $P_{24}$  becomes the OBF (Output Buffer Full) pin. A "1" written to  $P_{24}$  enables the OBF pin (the pin outputs the OBF Status Bit). A "0" written to  $P_{24}$  disables the OBF pin (the pin remains low). This pin can be used to indicate that valid data is available from the UPI-41A (in Output Data Bus Buffer).

If "EN FLAGS" has been executed,  $P_{25}$  becomes the  $\overline{\rm IBF}$  (Input Buffer Full) pin. A "1" written to  $P_{25}$  enables the  $\overline{\rm IBF}$  pin (the pin outputs the inverse of the IBF Status Bit). A "0" written to  $P_{25}$  disables the  $\overline{\rm IBF}$ 

pin (the pin remains low). This pin can be used to indicate that the UPI-42 is ready for data.

 P<sub>26</sub> and P<sub>27</sub> are port pins or DMA handshake pins for use with a DMA controller. These pins default to port pins on Reset.

put to step the program through

If the "EN DMA" instruction has been executed, P<sub>26</sub> becomes the DRQ (DMA ReQuest) pin. A "1" written to P<sub>26</sub> causes a DMA request (DRQ is activated). DRQ is deactivated by DACK·RD, DACK·WR, or execution of the "EN DMA" instruction.

If "EN DMA" has been executed,  $P_{27}$  becomes the DACK (DMA ACKnowledge) pin. This pin acts as a chip select input for the Data Bus Buffer registers during DMA transfers.

- The RESET input on the 8042/8742 includes a 2-stage synchronizer to support reliable reset operation for 12 MHz operation.
- 7. When EA is enabled on the 8042/8742, the program counter is placed on Port 1 and the lower three bits of Port 2 (MSB =  $P_{22}$ , LSB =  $P_{10}$ ). On the 8042/8742 this information is multiplexed with PORT DATA (see port timing diagrams at end of this data sheet).
- The 8042/8742 supports single step mode as described in the pin description section.

## PROGRAMMING, VERIFYING, AND ERASING THE 8742 EPROM

#### **Programming Verification**

In brief, the programming process consists of: activating the program mode, applying an address, latching the address, applying data, and applying a programming pulse. Each word is programmed completely before moving on to the next and is followed by a verification step. The following is a list of the pins used for programming and a description of their functions:

Pin	Function
XTAL 1	Clock Input (1 to 12MHz)
Reset	Initialization and Address Latching
Test 0	Selection of Program or Verify Mode
EA	Activation of Program/Verify Modes
BUS	Address and Data Input Data Output During Verify
P20-1	Address Input
V <sub>DD</sub>	Programming Power Supply
PROG	Program Pulse Input

#### WARNING

An attempt to program a missocketed 8742 will result in severe damage to the part. An indication of a properly socketed part is the appearance of the SYNC clock output. The lack of this clock may be used to disable the programmer.

#### The Program/Verify sequence is:

- A<sub>0</sub> = 0V, <del>CS</del> = 5V, EA = 5V, <del>RESET</del> = 0V, TEST0 = 5V, V<sub>DD</sub> = 5V, clock applied or internal oscillator operating, BUS and PROG floating.
- 2. Insert 8742 in programming socket
- 3. TEST 0 = 0v (select program mode)
- 4. EA = 21V (active program mode)\*
- 5. Address applied to BUS and P20-22
- 6. RESET = 5v (latch address)
- 7. Data applied to BUS\*\*
- 8. V<sub>DD</sub> = 21V (programming power)\*\*
- 9. PROG = 0v followed by one 50 ms pulse to 21V\*\*
- 10. V<sub>DD</sub> = 5v
- 11. TEST 0 = 5v (verify mode)

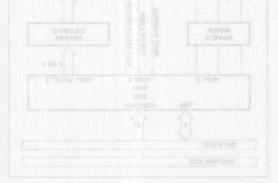

- 12. Read and verify data on BUS
- 13. TEST 0 = 0v
- 14. RESET = 0v and repeat from step 5
- Programmer should be at conditions of step 1 when 8742 is removed from socket

\*When verifying ROM, EA = 12V.

\*\*Not used in verifying ROM procedure.

#### 8742 Erasure Characteristics

The erasure characteristics of the 8742 are such that erasure begins to occur when exposed to light with wavelengths shorter than approximately 4000 Angstroms (Å). It should be noted that sunlight and certain types of fluorescent lamps have wavelengths in the 3000-4000Å range. Data show that constant exposure to room level fluorescent lighting could erase the typical 8742 in approximately 3 years while it would take ap-

proximately one week to cause erasure when exposed to direct sunlight. If the 8742 is to be exposed to these types of lighting conditions for extended periods of time, opaque labels are available from Intel which should be placed over the 8742 window to prevent unintentional erasure.

The recommended erasure procedure for the 8742 is exposure to shortwave ultraviolet light which has a wavelength of 2537Å. The integrated dose (i.e., UV intensity x exposure time) for erasure should be a minimum of 15 w-sec/cm². The erasure time with this dosage is approximately 15 to 20 minutes using an ultraviolet lamp with a 12,000  $\mu\text{W/cm}^2$  power rating. The 8742 should be placed within one inch of the lamp tubes during erasure. Some lamps have a filter on their tubes which should be removed before erasure.

#### ARITHMETIC PROCESSING UNIT

- Fixed Point Single and Double Precision (16/32 Bit)
- Floating Point Single Precision (32 Bit)
- Binary Data Formats
- Add, Subtract, Multiply and Divide
- Trigonometric and Inverse
   Trigonometric Functions
- Square Roots, Logarithms, Exponentiation
- Float to Fixed and Fixed to Float Conversions
- Stack Oriented Operand Storage

- Compatible with MCS-80<sup>TM</sup> and MCS-85<sup>TM</sup> Microprocessor Families
- Direct Memory Access or Programmed I/O Data Transfers
- End of Execution Signal
- General Purpose 8-Bit Data Bus Interface
- Standard 24 Pin Package
- + 12 Volt and + 5 Volt Power Supplies
- Advanced N-Channel Silicon Gate HMOS Technology

The Intel® 8231A Arithmetic Processing Unit (APU) is a monolithic HMOS LSI device that provides high performance fixed and floating point arithmetic and floating point trigonometric operations. It may be used to enhance the mathematical capability of a wide variety of processor-oriented systems. Chebyshev polynomials are used in the implementation of the APU algorithms.

All transfers, including operand, result, status and command information, take place over an 8-bit bidirectional data bus. Operands are pushed onto an internal stack and commands are issued to perform operations on the data in the stack. Results are then available to be retrieved from the stack.

Transfers to and from the APU may be handled by the associated processor using conventional programmed I/O, or may be handled by a direct memory access controller for improved performance. Upon completion of each command, the APU issues an end of execution signal that may be used as an interrupt by the CPU to help coordinate program execution.

In January 1981 Intel will be converting from 8231 to 8231A. The 8231A provides enhancements over the 8231 to allow use in both asynchronous and synchronous systems.

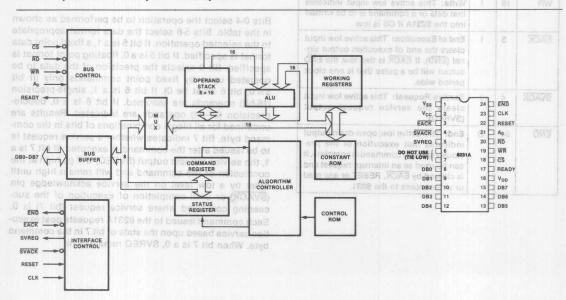

Figure 1. Block Diagram

Figure 2. Pin Configuration

#### Table 1. Pin Description

Symbol	Pin No.	Туре		Name and Function		
Vcc	2	ne "	Power	: +5 Volt power supply.		
V <sub>DD</sub>	16	641	Power	Power: +12 Volt power supply.		
V <sub>SS</sub>	1	- 1	Groun			
CLK	23	งร้างIcus	127 127 667 1	An external, TTL compatible,		
		1000		source is applied to the CLK pin.		
RESET	22	ews	Reset: The active high reset signal provides initialization for the chip. RESET also terminates any operation in progress. RESET clears the status register and places the 8231A into the idle state. State contents and command registers are not affected (5 clock cycles).			
CS et	18	1	signal	Chip Select: CS is an active low inpu signal which selects the 8231A and en ables communication with the data bus		
A <sub>0</sub> sometive rematica	ism	edt es	and W tablish that is t	<b>88:</b> In conjunction with the $\overline{\text{RD}}$ R signals, the $A_0$ control line esses the type of communication to be performed with the 8231A as below:		
Ao		RD	WR	Function		
d vanto	pile DUI	1 0 1 0	0 1 0	Enter data byte into stack Read data byte from stack Enter command Read status		
RD ituos	20	rojnar rojnar ine 82	that da	This active low input indicates ta or status is to be read from the if CS is low.		
WR	19	- 1	that da	This active low input indicates ta or a command is to be written e 8231A if CS is low.		
EACK	3	1	End of Execution: This active low input clears the end of execution output signal (END). If EACK is tied low, the END output will be a pulse that is one clock period wide.			
SVACK	4 GRE MAD TRANS		Service Request: This active low input clears the service request output (SVREQ).			
END	24° din NW 25 YOARA GEV 100	0 00 00 00 00 00 00 00 00 00 00 00 00 0	indicativiously can be is clear	This active low, open-drain output tes that execution of the pre- rentered command is complete. It used as an interrupt request and red by EACK, RESET or any read e access to the 8231.		

Symbol	Pin No.	Туре	Name and Function
SVREQ	5	0.	Service Request: This active high output signal indicates that command execution is complete and that post execution service was requested in the previous command byte. It is cleared by SVACK, the next command output to the device, or by RESET.
READY	17	.81 01 1	Ready: This active high output indicates that the 8231A is able to accept communication with the data bus. When an attempt is made to read data, write data or to enter a new command while the 8231A is executing a command, READY goes low until execution of the current command is complete (See READY Operation, p. 5).
DB0- DB7 s m s el (U	8- 15	I/O Sto InU or onits	Data Bus: These eight bidirectional lines provide for transfer of commands, status and data between the 8231A and the CPU. The 8231A can drive the data bus only when CS and RD are low.

#### COMMAND STRUCTURE

Each command entered into the 8231A consists of a single 8-bit byte having the format illustrated below:

SVREQ (R)	an actuacy to de lane			OPERATION			
	SINGLE	FIXED	havna	CODE	XO II	ante ma	Sanas
-	Parallel	o it gan	ondanu	DESCRIPTION OF THE PERSON OF T	200	dom en	PITISU I

Bits 0-4 select the operation to be performed as shown in the table. Bits 5-6 select the data format appropriate to the selected operation. If bit 5 is a 1, a fixed point data format is specified. If bit 5 is a 0, floating point format is specified. Bit 6 selects the precision of the data to be operated upon by fixed point commands only (if bit 5 = 0, bit 6 must be 0). If bit 6 is a 1, single-precision (16-bit) operands are assumed. If bit 6 is a 0, doubleprecision (32-bit) operands are indicated. Results are undefined for all illegal combinations of bits in the command byte. Bit 7 indicates whether a service request is to be issued after the command is executed. If bit 7 is a 1, the service request output (SVREQ) will go high at the conclusion of the command and will remain high until reset by a low level on the service acknowledge pin (SVACK) or until completion of execution of the succeeding command where service request (bit 7) is 0. Each command issued to the 8231A requests post execution service based upon the state of bit 7 in the command byte. When bit 7 is a 0, SVREQ remains low.

Notes: 1. In the hex code column, SVREQ is a 0.

2. The stack initially is composed of four 32-bit numbers (A, B, C, D). A is equivalent to Top Of Stack (TOS) and B is Next On Stack (NOS). Upon completion of a command the stack is composed of: the result (R); undefined (U); or the initial contents (A, B, C, or D).

3. The stack initially is composed of eight 16-bit numbers (A<sub>U</sub>, A<sub>L</sub>, B<sub>U</sub>, B<sub>L</sub>, C<sub>U</sub>, C<sub>L</sub>, D<sub>U</sub>, D<sub>L</sub>). A<sub>U</sub> is the TOS and A<sub>L</sub> is NOS. Upon completion of a command the stack is composed of: the result (R); undefined (U); or the initial contents (A<sub>U</sub>, A<sub>L</sub>, B<sub>U</sub>, B<sub>L</sub>, . . .).

4. Nomenclature: Sign (S); Zero (Z); Overflow (O); Carry (C); Error Code Field (E).

# DATA FORMATS

The 8231A arithmetic processing unit handles operands in both fixed point and floating point formats. Fixed point operands may be represented in either single (16-bit operands) or double precision (32-bit operands), and are always represented as binary, two's complement values.

# SINGLE PRECISION FIXED POINT FORMAT

# DOUBLE PRECISION FIXED POINT FORMAT

The sign (positive or negative) of the operand is located in the most significant bit (MSB). Positive values are represented by a sign bit of zero (S = 0). Negative values are represented by the two's complement of the corresponding positive value with a sign bit equal to 1 (S = 1). The range of values that may be accommodated by each of these formats is  $-32,768\ to +32,767\ for\ single\ precision and <math display="inline">-2,147,483,648\ to +2,147,483,647\ for\ double\ precision.$ 

Floating point binary values are represented in a format that permits arithmetic to be performed in a fashion analogous to operations with decimal values expressed in scientific notation.

$$(5.83 \times 10^2) (8.16 \times 10^1) = (4.75728 \times 10^4)$$

In the decimal system, data may be expressed as values between 0 and 10 times 10 raised to a power that effectively shifts the implied decimal point right or left the number of places necessary to express the result in conventional form (e.g., 47,572.8). The value-portion of the data is called the mantissa. The exponent may be either negative or positive.

The concept of floating point notation has both a gain and a loss associated with it. The gain is the ability to represent the significant digits of data with values spanning a large dynamic range limited only by the capacity of the exponent field. For example, in decimal notation if the exponent field is two digits wide, and the mantissa is five digits, a range of values (positive or negative) from  $1.0000 \times 10^{-99}$  to  $9.9999 \times 10^{+99}$  can be accommodated. The loss is that only the significant digits of the value can be represented. Thus there is no distinction in this representation between the values 123451 and 123452, for example, since each would be expressed as: 1.2345 x 105. The sixth digit has been discarded. In most applications where the dynamic range of values to be represented is large, the loss of significance, and hence accuracy of results, is a minor consideration. For greater precision a fixed point format could be chosen, although with a loss of potential dynamic range.

The 8231A is a binary arithmetic processor and requires that floating point data be represented by a fractional mantissa value between .5 and 1 multiplied by 2 raised to an appropriate power. This is expressed as follows:

For example, the value 100.5 expressed in this form is  $0.1100\ 1001 \times 2^7$ . The decimal equivalent of this value may be computed by summing the components (powers of two) of the mantissa and then multiplying by the exponent as shown below:

value = 
$$(2^{-1} + 2^{-2} + 2^{-5} + 2^{-8}) \times 2^7$$
  
=  $0.5 + 0.25 + 0.03125 + 0.00290625) \times 128$   
=  $0.78515625 \times 128$   
=  $100.5$ 

# FLOATING POINT FORMAT

The format for floating point values in the 8231A is given below. The mantissa is expressed as a 24-bit (fractional) value; the exponent is expressed as a two's complement 7-bit value having a range of -64 to +63. The most significant bit is the sign of the mantissa (0 = positive, 1 = negative), for a total of 32 bits. The binary point is assumed to be to the left of the most significant mantissa bit (bit 23). All floating point data values must be normalized. Bit 23 must be equal to 1, except for the value zero, which is represented by all zeros.

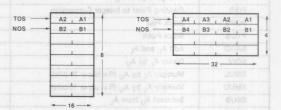

The range of values that can be represented in this format is  $\pm (2.7 \times 10^{-20} \text{ to } 9.2 \times 10^{18})$  and zero.

# **FUNCTIONAL DESCRIPTION**

#### STACK CONTROL

The user interface to the 8231A includes access to an 8 level 16-bit wide data stack. Since single precision fixed point operands are 16-bits in length, eight such values may be maintained in the stack. When using double precision fixed point or floating point formats four values may be stored. The stack in these two configurations can be visualized as shown below:

Data are written onto the stack, eight bits at a time, in the order shown (A1, A2, A3, ...). Data are removed from the stack in reverse byte order (A4, A3, A2...). Data should be entered onto the stack in multiples of the number of bytes appropriate to the chosen data format.

# cution, these times will be heavily influYRTMA ATAC

Data entry is accomplished by bringing the chip select  $(\overline{CS})$ , the command/data line  $(A_0)$ , and  $\overline{WR}$  low, as shown in the timing diagram. The entry of each new data word "pushes down" the previously entered data and places the new byte on the top of stack (TOS). Data on the bottom of the stack prior to a stack entry are lost.

#### DATA REMOVAL

Data are removed from the stack in the 8231A by bringing chip select  $(\overline{CS})$ , command/data  $(A_0)$ , and  $\overline{RD}$  low as shown in the timing diagram. The removal of each data word redefines TOS so that the next successive byte to be removed becomes TOS. Data removed from the stack rotates to the bottom of the stack.

### **COMMAND ENTRY**

After the appropriate number of bytes of data have been entered onto the stack, a command may be issued to perform an operation on that data. Commands which require two operands for execution (e.g., add) operate on the TOS and NOS values. Single operand commands operate only on the TOS.

Commands are issued to the 8231A by bringing the chip select  $(\overline{CS})$  line low, command data  $(A_0)$  line high, and  $\overline{WR}$  line low as indicated by the timing diagram. After a command is issued, the CPU can continue execution of its program concurrently with the 8231A command execution.

# COMMAND COMPLETION

The 8231A signals the completion of each command execution by lowering the End Execution line (END). Simultaneously, the busy bit in the status register is cleared and the Service Request bit of the command register is checked. If it is a "1" the service request output level (SVREQ) is raised. END is cleared on receipt of an active low End Acknowledge (EACK) pulse. Similarly, the service request line is cleared by recognition of an active low Service Acknowledge (SVACK) pulse.

#### **READY OPERATION**

An active high ready (READY) is provided. This line is high in its quiescent state and is pulled low by the 8231A under the following conditions:

- A previously initiated operation is in progress (device busy) and Command Entry has been attempted. In this case, the READY line will be pulled low and remain low until completion of the current command execution. It will then go high, permitting entry of the new command.
- A previously initiated operation is in progress and stack access has been attempted. In this case, the READY line will be pulled low, will remain in that state until execution is complete, and will then be raised to permit completion of the stack access.
- 3. The 8231A is not busy, and data removal has been requested. READY will be pulled low for the length of time necessary to transfer the byte from the top of stack to the interface latch, and will then go high, indicating availability of the data.

- 4. The 8231A is not busy, and a data entry has been requested. READY will be pulled low for the length of time required to ascertain if the preceding data byte, if any, has been written to the stack. If so READY will immediately go high. If not, READY will remain low until the interface latch is free and will then go high.
- 5. When a status read has been requested, READY will be pulled low for the length of time necessary to transfer the status to the interface latch, and will then be raised to permit completion of the status read. Status may be read whether or not the 8231A is busy.

When READY goes low, the APU expects the bus control signals present at the time to remain stable until READY goes high.

# **DEVICE STATUS**

Device status is provided by means of an internal status register whose format is shown below:

BUSY: Indicates that 8231A is currently executing a command (1=Busy)

SIGN: Indicates that the value on the top of stack is negative (1 = Negative)

ZERO: Indicates that the value on the top of stack is zero (1 = Value is zero)

ERROR CODE: This field contains an indication of the validity of the result of the last operation. The error codes are:

(A) 0000 — No error, A 4 8 X A 4 8 X A 4 X A 4 A A = (X)

1000 - Divide by zero

0100 — Square root or log of negative number

1100 — Argument of inverse sine, cosine, or e<sup>x</sup> too large

MOXX10 - Underflow a dilW Jiame et |X| nodw Ilame

Vne XX01 - Overflow sham at not fud high none ent

CARRY: Previous operation resulted in carry or borrow from most significant bit. (1 = Carry/Borrow, 0 = No Carry/No Borrow.)

If the BUSY bit in the status register is a one, the other status bits are not defined; if zero, indicating not busy, the operation is complete and the other status bits are defined as given above.

### **READ STATUS**

The 8231A status register can be read by the CPU at any time (whether an operation is in progress or not) by bringing the chip select  $\overline{(CS)}$  low, the command/data line  $(A_0)$  high, and lowering  $\overline{RD}$ . The status register is then gated onto the data bus and may be input by the CPU.

# **EXECUTION TIMES**

Timing for execution of the 8231A command set is contained below. All times are given in terms of clock cycles. Where substantial variation of execution times

is possible, the minimum and maximum values are quoted; otherwise, typical values are given. Variations are data dependent.

Total execution times may require allowances for operand transfer into the APU, command execution, and result retrieval from the APU. Except for command exe-

cution, these times will be heavily influenced by the nature of the data, the control interface used, the speed of memory, the CPU used, the priority allotted to DMA and Interrupt operations, the size and number of operands to be transferred, and the use of chained calculations, etc.

# DERIVED FUNCTION DISCUSSION DELICARIO

Computer approximations of transcendental functions are often based on some form of polynomial equation, such as:

$$F(X) = A_0 + A_1X + A_2X^2 + A_3X^3 + A_4X^4 + \cdots$$
 (1-1)

The primary shortcoming of an approximation in this form is that it typically exhibits very large errors when the magnitude of |X| is large, although the errors are small when |X| is small. With polynomials in this form, the error distribution is markedly uneven over any arbitrary interval.

A set of approximating functions exists that not only minimizes the maximum error but also provides an even distribution of errors within the selected data representation interval. These are known as Chebyshev Polynomials and are are based upon cosine functions. These functions are defined as follows:

$$T_n(X) = \cos n\theta$$
; where  $n = 0,1,2...$  (1-2  $\theta = \cos^{-1}X$ 

The various terms of the Chebyshev series can be computed as shown below:

$$T_0(X) = Cos(0 \cdot \theta) = Cos(0) = 1$$
 (1-4)  
 $T_1(X) = Cos(Cos^{-1}X) = X$  (1-5)

$$T_2(X) = \cos 2\theta = 2\cos^2 \theta - 1 = 2\cos^2(\cos^{-1}X) - 1$$
 (1-6)  
=  $2X^2 - 1$ 

In general, the next term in the Chebyshev series can be recursively derived from the previous term as follows:

$$T_n(X) = 2X [T_n - 1(X)] - T_n - 2(X); n \ge 2\pi i$$
 visuoenati (1-7) bnammoo adi to iid iseupen soivie2 adi bna berselo

Common logarithms are computed by multiplication of the natural logarithm by the conversion factor 0.43429448 and the error function is therefore the same as that for natural logarithm. The power function is realized by combination of natural log and exponential functions according to the equation:

$$X^{Y} = e^{yLnx}$$
.

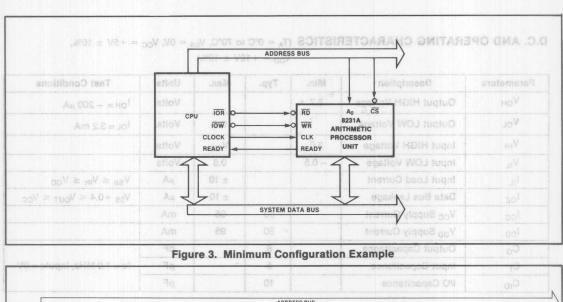

The error for the power function is a combination of that for the logarithm and exponential functions.

Each of the derived functions is an approximation of the true function. Thus the result of a derived function will have an error. The absolute error is the difference between the function's result and the true result. A more useful measure of the function's error is relative error (absolute error/true result). This gives a measurement of the significant digits of algorithm accuracy. For the derived functions except LN, LOG, and PWR the relative error is typically  $4\times 10^{-7}.$  For PWR the relative error is the summation of the EXP and LN errors,  $7\times 10^{-7}.$  For LN and LOG, the absolute error is  $2\times 10^{-7}.$ 

tions for the APU with operand transfers handled by an 8237 DMA controller, and CPU coordination handled by an Interrupt Controller. The APU interrupts the CPU to indicate that a command has been completed. When the performance enhancements provided by the DMA and Interrupt operations are not required, the APU interface

any general 8-bit processor.

In many systems it will be convenient to use the microcomputer system clock to drive the APU clock input. In the case of 8080A systems it would be the \$\phi2TTL\$ signal. Its cycle time will usually fall in the range of 250 ns to 1000 ns, depending on the system speed.

#### NOTES

- 1. Typical values are for T<sub>A</sub>=25°C, nominal supply voltages and nominal processing parameters.
- 2. READY is pulled low for both command and data operations.
- Minimum values shown assume no previously entered command is being executed for the data access. If a previously entered command is being executed, READY low pulse width is the time to complete execution plus the time shown. Status may be read at any time without exceeding the time shown.
- 4. READY low pulse width is less than 50 ns when writing into the data port or the control port as long as the duty cycle requirement (t<sub>WI</sub>) is observed and no previous command is being executed. t<sub>WI</sub> may be safely violated as long as the extended t<sub>RRW</sub> that results is observed. If a previously entered command is being executed, READY low pulse width is the time to complete execution plus the time shown. These timings refer specifically to the 8231A.
- 5. END low pulse width is specified for EACK tied to VSS. Otherwise teae applies.

EACK

# FLOATING POINT PROCESSING UNIT

- Compatible with Proposed IEEE Format and Existing Intel Floating Point Standard
- Single (32-Bit) and Double (64-Bit)
   Precision Capability
- Add, Subtract, Multiply and Divide Functions
- Stack Oriented Operand Storage
- General Purpose 8-Bit Data Bus Interface

- Standard 24-Pin Package
- 12V and 5V Power Supplies
- Compatible with MCS-80<sup>TM</sup>, MCS-85<sup>TM</sup> and MCS-86<sup>TM</sup> Microprocessor Families
- Error Interrupt
- Direct Memory Access or Programmed
   I/O Data Transfers
- End of Execution Signal
- Advanced N-Channel Silicon Gate HMOS Technology

The Intel® 8232 is a high performance floating-point processor unit (FPU). It provides single precision (32-bit) and double precision (64-bit) add, subtract, multiply and divide operations. The 8232's floating point arithmetic is a subset of the proposed IEEE standard. It can be easily interfaced to enhance the computational capabilities of the host microprocessor.

The operand, result, status and command information transfers take place over an 8-bit bidirectional data bus. Operands are pushed onto an internal stack by the host processor and a command is issued to perform an operation on the data stack. The results of the operation are available to the host processor from the stack.

Information transfers between the 8232 and the host processor can be handled by using programmed I/O or direct memory access techniques. After completing an operation, the 8232 activates an "end of execution" signal that can be used to interrupt the host processor.

# FUNCTIONAL DESCRIPTION

Major functional units of the 8232 are shown in the block diagram. The 8232 employs a microprogram controlled stack oriented architecture with 17-bit wide data paths.

The Arithmetic Unit receives one of its operands from the Operand Stack. This stack is an eight word by 17-bit two port memory with last in-first out (LIFO) attributes. The second operand to the Arithmetic Unit is supplied by the internal 17-bit bus. In addition to supplying the second operand, this bidirectional bus also carries the results from the output of the Arithmetic Unit when required. Writing into the Operand Stack takes place

from this internal 17-bit bus when required. Also connected to this bus are the Constant ROM and Working Registers. The ROM provides the required constants to perform the mathematical operations while the Working Registers provide storage for the intermediate values during command execution.

Communication between the external world and the 8232 takes place on eight bidirectional input/output lines, DB0 through DB7 (Data Bus). These signals are gated to the internal 8-bit bus through appropriate interface and buffer circuitry. Multiplexing facilities exist for bidirectional communication between the internal eight

and 17-bit buses. The Status Register and Command and Register are also located on the 8-bit bus.

The 8232 operations are controlled by the microprogram contained in the Control ROM. The Program Counter supplies the microprogram addresses and can be partially loaded from the Command Register. Associated with the Program Counter is the Subroutine Stack where return addresses are held during subroutine calls in the microprogram. The Microinstruction Register holds the current microinstruction being executed. The register facilitates pipelined microprogram execution. The Instruction Decode logic generates various internal control signals needed for the 8232 operation.

The Interface Control logic receives several external inputs and provides handshake related outputs to facilitate interfacing the 8232 to microprocessors.

# **Command Format**

The operation of the 8232 is controlled from the host processor by issuing instructions called commands. The command format is shown below.

The command consists of 8 bits; the least significant 7 bits specify the operation to be performed as detailed in Table 1. The most significant bit is the Service Request Enable bit. This bit must be a 1 if SVREQ is to go HIGH at the end of executing a command.

The commands fall into three categories: single precision arithmetic, double precision arithmetic and data manipulation. There are four arithmetic operations that can be performed with single precision (32-bit) or double precision (64-bit) floating-point numbers; add, subtract. multiply and divide. These operations require two operands. The 8232 assumes that these operands are located in the internal stack as Top of Stack (TOS) and Next on Stack (NOS). The result will always be returned to the previous NOS which becomes the new TOS. Results from an operation are of the same precision and format as the operands. The results will be rounded to preserve the accuracy. The actual data formats and rounding procedures are described in a later section. In addition to the arithmetic operations, the 8232 implements eight data manipulating operations. These include changing the sign of a double or single precision operand located in TOS, exchanging single precision operands located at TOS and NOS, as well as pushing and popping single or double precision operands. See also the sections on status register and operand formats.

The execution times of the commands are all data dependent. Table 3 shows one example of each command execution time.

# **Operand Entry**

The 8232 commands operate on the operands located at the TOS and NOS. Results are returned to the stack at NOS and then popped to TOS. The operands required for the 8232 are one of two formats — single precision floating-point (4 bytes) or double precision floating-point (8 bytes). The result of an operation has the same format as the operands. In other words, operations using single precision quantities always result in a single precision result, while operations involving double precision quantities will result in double precision result.

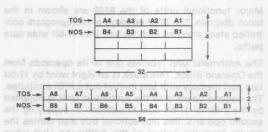

Operands are always entered into the stack least significant byte first and most significant byte last. The following procedure must be followed to enter operands into the stack:

- 1. The lower significant operand byte is established on the DB0-DB7 lines.
- A LOW is established on the A<sub>0</sub> input to specify that data is to be entered into the stack.
- The CS input is made LOW. Whenever the WR and RD inputs are HIGH, the READY output will follow the CS input. Thus, READY output will become LOW.
- After appropriate set up time (see timing diagrams), the WR input is made LOW.
- Sometime after this event, READY will return HIGH to indicate that the write operation has been acknowledged.
- Any time after the READY output goes HIGH, the WR input can be made HIGH. The DB0-DB7, A<sub>0</sub> and CS inputs can change after appropriate hold time requirements are satisfied (see timing diagrams).

The above procedure must be repeated until all bytes of the operand are pushed into the stack. It should be noted that for single precision operands 4 bytes should be pushed and 8 bytes must be pushed for double precision. Not pushing all the bytes of a quantity will result in byte pointer misalignment.

The 8232 stack can accommodate four single precision quantities or two double precision quantities. Pushing more quantities than the capacity of the stack will result in loss of data which is usual with any LIFO stack.

The stack can be visualized as shown below:

required. Writing into the Operand Stack takes place

Note: TOS, NOS and result are in hexadecimal; clock period is in decimal.

# Command Initiation

After properly positioning the required operands in the stack, a command may be issued. The procedure for initiating a command execution is the same as that described above for operand entry, except that the  $A_0$  input is HIGH.

An attempt to issue a new command while the current command execution is in progress is allowed. Under these circumstances, the READY output will not go HIGH until the current command execution is completed.

# Removing the Results

Result from an operation will be available at the TOS. Results can be transferred from the stack to the data bus by reading the stack.

When the stack is read for results, the most significant byte is available first and the least significant byte last.

A result is always of the same precision as the operands that produced it. Thus, when the result is taken from the stack, the total number of bytes popped out should be appropriate with the precision — single precision results are 4 bytes and double precision results are 8 bytes. The following procedure must be used for reading the result from the stack:

- 1. A LOW is established on the Ao input.
- The CS input is made LOW. When WR and RD inputs are both HIGH, the READY output follows the CS input, thus READY will be LOW.
- After appropriate set up time (see timing diagrams), the RD input is made LOW.

- Sometime after this, READY will return HIGH, indicating that the data is available on the DB0-DB7 lines. This data will remain on the DB0-DB7 lines as long as the RD input remains LOW.
- 5. Any time after READY goes HIGH, the RD input can return HIGH to complete the transaction.
- The CS and A<sub>0</sub> inputs can change after appropriate hold time requirements are satisfied (see timing diagram).
- Repeat this procedure until all bytes appropriate for the precision of the result are popped out.

Reading of the stack does not alter its data; it only adjusts the byte pointer. Note data must be removed in even byte multiples to avoid a byte pointer misalignment. If more data is popped than the capacity of the stack, the internal byte pointer will wrap around and older data will be read again, consistent with the LIFO stack.

# Reading Status Register source at villation losses and

The 8232 status register can be read without any regard to whether a command is in progress or not. The only implication that has to be considered is the effect this might have on the END and ERROR outputs discussed in the signal descriptions.

The following procedure must be followed to accomplish status register reading:

- 1. Establish HIGH on the Ao input.
- Establish LOW on the CS input. Whenever WR and RD inputs are HIGH, READY will follow the CS input. Thus, READY will go LOW.
- After appropriate set up time (see timing diagram), RD is made LOW.

- 4. Sometime after the HIGH to LOW transition of RD. READY will become HIGH, indicating that status register contents are available on the DB0-DB7 lines. These lines will contain this information as long as RD is LOW.
- 5. The RD input can be returned HIGH any time after READY goes HIGH. I be sollalinged a not aldiscou
- 6. The Ao input and CS input can change after satisfying appropriate hold time requirements (see timing diagram). The best example of what might be called the 8232's

# Status Register bisup to eareads ent animuon

The 8232 contains an 8-bit status register with the following format:

BUSY	SIGN	ZERO Z	RESERVED	DIVIDE EXCEPTION D	EXPONENT UNDERFLOW	EXPONENT OVERFLOW V	RESERVED
7	6	5	itemana	3	2	int the Le	0

All the bits are initialized to zero upon reset. Also, executing a CLR (Clear Status) command will result in all zero status register bits. A zero in bit 7 indicates that the 8232 is not busy and a new command may be initiated. As soon as a new command is issued, bit 7 becomes 1 to indicate the device is busy and remains 1 until the command execution is complete, at which time it will become 0. As soon as a new command is issued. status register bits 0-6 are cleared to zero. The status bits will be set as required during the command execution. Hence, as long as bit 7 is 1, the remainder of the status register bit indications should not be relied upon unless the ERROR occurs. The following is a detailed status bit description.

- Bit 0 Reserved ob of -(2) lid "vylolid" eff bits (R) lid
- Bit 1 Exponent overflow (V). When 1, this bit indicates that the result exponent is more positive than + 127 (+ 1023). The exponent is "wrapped" into the negative exponent range, skipping the end values.
- Bit 2 Exponent Underflow (U). When 1, this bit indicates that the result exponent is more negative than -126 (-1022). The exponent is "wrapped" into the positive range by the number of underflow bits. skipping -127 (-1023) and +128 (+1024).
- Bit 3 Divide Exception (D). When 1, this bit indicates that an attempt to divide by zero is made. Cleared to zero otherwise.
- Bit 4 Reserved.
- Bit 5 Zero (Z). When 1, this bit indicates that the result returned to TOS after a command is zero. Cleared to zero otherwise.
- Bit 6 Sign (S). When 1, this bit indicates that the result returned to TOS is negative. Cleared to zero otherwise.

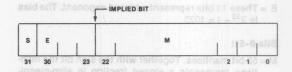

Bit 7 Busy. When 1, this bit indicates the 8232 is in the process of executing a command. It will become zero after the command execution is complete.

All other status register bits are valid when the Busy bit is zero.

# **Data Formats**

The 8232 handles floating-point quantities in two different formats - single precision and double precision. These formats are the same as those used by Intel in other products and those proposed by the IEEE Subcommittee on floating point arithmetic.

The single precision quantities are 32 bits long, as shown below:

# tude notation. There is an implied 1 beyond

Bit 31: I seement to (to tid) it dissifingle from S = Sign of the mantissa. One represents negative and 0 represents positive.

will always be a 1 due to normalization, is

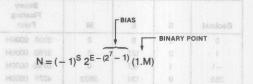

#### Bits 23-30; methi fid beilgmi sint seroteer 9898 edit

E = These 8 bits represent a biased exponent. The bias is 27 - 1 = 127. usnid effT and also lamete efft

#### Bits 0-22:

M = 23-bit mantissa. Together with the sign bit, the mantissa represents a signed fraction in sign-magnitude notation. There is an implied 1 beyond the most significant bit (bit 22) of the mantissa. In other words, the mantissa is assumed to be a 24-bit normalized quantity and the most significant bit, which will always be a 1 due to normalization, is implied. The 8232 restores this implied bit internally before performing arithmetic, normalizes the result and strips the implied bit before returning the results to the external data bus. The binary point is between the implied bit and bit 22 of the mantissa.

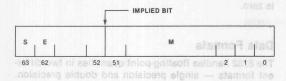

The quantity N represented by the above notation is

Provided E+0 (reserved for 0) or all 1's (illegal). The approximate decimal range for this format is  $\pm 1.17 \times 10^{-38}$  to  $\pm 3.40 \times 10^{38}$ . The format supports 7 significant decimal digits.

A double precision quantity consists of the mantissa sign bit, an 11-bit biased exponent (E), and a 52-bit mantissa (M). The bias for double precision quantities is  $2^{10} - 1$ . The double precision format is illustrated below.

# Bit 63: Vd besu eson) as emas ent era stemon esent

S = Sign of the mantissa. One represents negative and 0 represents positive.

# Bits 52-62:

E = These 11 bits represent a biased exponent. The bias is  $2^{10} - 1 = 1023$ .

#### Bits 0-51:

M = 52-bit mantissa. Together with the sign bit the mantissa represents a signed fraction in sign-magnitude notation. There is an implied 1 beyond the most significant bit (bit 51) of the mantissa. In other words, the mantissa is assumed to be a 53-bit normalized quantity and the most significant bit, which will always be a 1 due to normalization, is implied. The 8232 restores this implied bit internally before performing arithmetic, normalizes the result and strips the implied bit before returning the result to the external data bus. The binary point is between the implied bit and bit 51 of the mantissa.

The quantity N represented by the above notation is

BIAS BINARY POINT 
$$N = (-1)^S 2^{E - (2^{10} - 1)} (1.M)$$

Provided E  $\neq$  0 (reserved for 0) or all 1s (illegal). The approximate decimal range is  $\pm 2.22 \times 10^{-308}$  to  $\pm 1.80 \times 10^{308}$ . The format supports 16 significant decimal digits.

The following are some examples of single precision floating point representations:

Decimal	s	E <sup>ANS</sup>	М	Binary Floating Point
0 1410	0	0	0	0000 0000H
1	0	127	. 0	3F80 0000H
-1	1	127	0	BF80 0000H
255	0	134	.9922	437F 0000H
T MEDELL	0	128	.5708	4049 OFDBH

 $\pm 1.17 \times 10^{-38}$  to  $\pm 3.40 \times 10^{36}$ . The former supports 7

# 4. Sometime after the HGH to LOW trans gnibnoz .

One of the main objectives in choosing the 8232's Intel/ IEEE proposed floating point arithmetic was to provide maximum accuracy with no anomalies. This means that a mathematically unsophisticated user will not be "surprised" by some of the results. It is probably possible for a sophisticated user to obtain reliable results from almost any floating point arithmetic. However, in that case there will be an additional burden on the software.

The best example of what might be called the 8232's "safety factor" is the inclusion of guard bits for rounding. The absence of guard bits leads to the problem demonstrated by the following four-bit multiplication:

$$\begin{array}{c} .1111 \times 2^{0} \\ 1000 \times 2^{1} \\ \hline \text{VARIABLE} & .011111000 \times 2^{1} \\ \end{array}$$

Since the last four bits are lost, the normalized result is:

and the identify function is not valid. In the past this problem has been avoided (hopefully) by relying on excess precision.

Instead the 8232 uses a form of rounding known as "round to even." There are other types of rounding provided for in the proposed IEEE standard, but "round to even," an unbiased rounding scheme, is required. "Round to even" comes into play when a result is exactly halfway between two floating point numbers. In this case the arithmetic produces the "even" number, the one whose last mantissa bit is zero. The 8232 uses three additional bits—the Guard bit (G), the Rounding bit (R), and the "Sticky" bit (S)—to do the rounding. These are bits which hold data shifted out (right) of the accumulator. Rounding is carried out by the following rules, as shown in the following figure, after the result is normalized.

ant olat "b stid wolft G Ac	DIL	menogxe en mun entry	Positive range t Rule

# **APPLICATIONS INFORMATION**

The diagram in Figure 3 represents the minimum configuration of an 8232 system. The CPU transfers data to and from the 8232 Floating Point Processor using the READY line. The 8232 status is checked using polling by the CPU.

In a high performance configuration (Figure 4), interrupts are used in place of polling. The interrupts are generated for an error condition and to signal the end of execution. Operand transfers are handled by the DMA controller.

#### NOTES:

- 1. Typical values are for T<sub>A</sub> = 25 °C, nominal supply voltages and nominal processing parameters.
- 2. READY is pulled low for both command and data operations.
- Minimum values shown assume no previously entered command is being executed for the data access. If a previously entered command is being
  executed, READY low pulse width is the time to complete execution plus the time shown. Status may be read at any time without exceeding the time
  shown.
- 4. END high pulse width is specified for EACK tied to VSS. Otherwise tEAE applies.

- **80 Byte/Sec Data Conversion Rate**
- 64-Bit Data Encryption Using 56-Bit Key
- DMA Interface
- 3 Interrupt Outputs to Aid in Loading and Unloading Data

- 7-Bit User Output Port
- Single 5V ± 10% Power Supply
- Peripheral to MCS-86<sup>TM</sup>, MCS-85<sup>TM</sup>, MCS-80<sup>TM</sup> and MCS-48<sup>TM</sup> Processors
- Implements Federal Information
   Processing Data Encryption Standard
- **Encrypt and Decrypt Modes Available**

The Intel® 8294 Data Encryption Unit (DEU) is a microprocessor peripheral device designed to encrypt and decrypt 64-bit blocks of data using the algorithm specified in the Federal Information Processing Data Encryption Standard. The DEU operates on 64-bit text words using a 56-bit user-specified key to produce 64-bit cipher words. The operation is reversible: if the cipher word is operated upon, the original text word is produced. The algorithm itself is permanently contained in the 8294; however, the 56-bit key is user-defined and may be changed at any time.

The 56-bit key and 64-bit message data are transferred to and from the 8294 in 8-bit bytes by way of the system data bus. A DMA interface and three interrupt outputs are available to minimize software overhead associated with data transfer. Also, by using the DMA interface two or more DEUs may be operated in parallel to achieve effective system conversion rates which are virtually any multiple of 80 bytes/second. The 8294 also has a 7-bit TTL compatible output port for user-specified functions.

Because the 8294 implements the NBS encryption algorithm it can be used in a variety of Electronic Funds Transfer applications as well as other electronic banking and data handling applications where data must be encrypted.

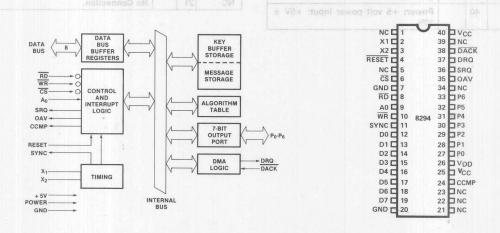

Figure 1. Block Diagram

# FUNCTIONAL DESCRIPTION

The data conversion sequence is as follows:

- A Set Mode command is given, enabling the desired as interrupt outputs.
- An Enter New Key command is issued, followed by 8
  data inputs which are retained by the DEU for encryption/decryption. Each byte must have odd parity.
- An Encrypt Data or Decrypt Data command sets the DEU in the desired mode.

After this, data conversions are made by writing 8 data bytes and then reading back 8 converted data bytes. Any of the above commands may be issued between data conversions to change the basic operation of the DEU; e.g., a Decrypt Data command could be issued to change the DEU from encrypt mode to decrypt mode without changing either the key or the interrupt outputs enabled.

# **INTERNAL DEU REGISTERS**

Four internal registers are addressable by the master processor: 2 for input, and 2 for output. The following table describes how these registers are accessed.

RD	WR	CS	A <sub>0</sub>	Register
1	0	0	0	Data input buffer
0	1	0	0	Data output buffer
1	0	0 0	=381	Command input buffer
0	1	0	1	Status output buffer
X	X	1	X	Don't care

The functions of each of these registers are described below.

**Data Input Buffer** — Data written to this register is interpreted in one of three ways, depending on the preceding command sequence.

- 1. Part of a key.
- 2. Data to be encrypted or decrypted.
- 3. A DMA block count.

**Data Output Buffer** — Data read from this register is the output of the encryption/decryption operation.

Command Input Buffer — Commands to the DEU are written into this register. (See command summary below.)

Status Output Buffer — DEU status is available in this register at all times, It is used by the processor for poll-driven command and data transfer operations.

STATUS BIT: FUNCTION: 7 6 5 4 3 2 1 0 X X X KPE CF DEC IBF OBF

OBF Output Buffer Full; OBF = 1 indicates that output from the encryption/decryption function is available in the Data Output Buffer. It is reset when the data is read.

- IBF Input Buffer Full; A write to the Data Input Buffer or to the Command Input Buffer sets IBF = 1. The DEU resets this flag when it has accepted the input byte. Nothing should be written when IBF = 1.
- DEC Decrypt; indicates whether the DEU is in an encrypt or a decrypt mode. DEC=1 implies the decrypt mode. DEC=0 implies the encrypt mode.
- CF Completion Flag; This flag may be used to indicate any or all of three events in the data transfer protocol.
- 1. It may be used in lieu of a counter in the processor routine to flag the end of an 8-byte transfer.
- to eat 12. It must be used to indicate the validity of
  - It may be used in lieu of the CCMP interrupt to indicate the completion of a DMA operation.

KPE Key Parity Error; After a new key has been entered, the DEU uses this flag in conjunction with the CF flag to indicate correct or incorrect parity.

# **COMMAND SUMMARY**

# 1 - Enter New Key

OP CODE:

0	1	0	0	0	0	0	(
---	---	---	---	---	---	---	---

This command is followed by 8 data byte inputs which are retained in the key buffer (RAM) to be used in encrypting and decrypting data. These data bytes must have odd parity represented by the LSB.

# 2 — Encrypt Data

OP CODE:

0	0	1	1	0	0	0	0
us	R		-				9

This command puts the 8294 into the encrypt mode.

#### 3 — Decrypt Data

OP CODE:

0	0	1	0	0	0	0	0
---	---	---	---	---	---	---	---

This command puts the 8294 into the decrypt mode.

# 4 - Set Mode

OP CODE:

0	0	0	0	A	В	С	D
VIS	В		14,				LSE

# where:

A is the OAV (Output Available) interrupt enable
B is the SRQ (Service Request) interrupt enable
C is the DMA (Direct Memory Access) transfer enable

D is the CCMP (Conversion Complete) interrupt enable

SRQ, or CCMP interrupts respectively. A "1" in bit C will allow DMA transfers. When bit C is set the OAV and SRQ interrupts should also be enabled (bits A,B = 1). Following the command in which bit C, the DMA bit, is set, the 8294 will expect one data byte to specify the number of 8-byte blocks to be converted using DMA.

This command causes the 7 least significant bits of the command byte to be latched as output data on the 8294 output port. The initial output data is 1111111. Use of this port is independent of the encryption/decryption function.

# PROCESSOR/DEU INTERFACE PROTOCOL ENTERING A NEW KEY

The timing sequence for entering a new key is shown in Figure 3. A flowchart showing the CPU software to accommodate this sequence is given in Figure 4.

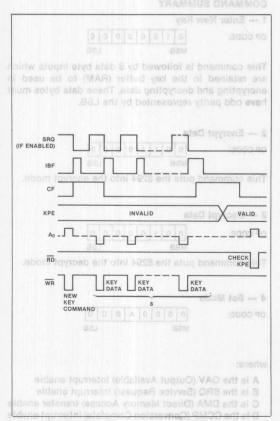

Figure 3. Entering a New Key

input buffer (most significant byte first). After the eighth byte is accepted by the DEU, CF goes true (CF = 1). The CF bit goes false again when KPE is valid. The CPU can then check the KPE flag. If KPE = 1, a parity error has been detected and the DEU has not accepted the key. Each byte is checked for odd parity, where the parity bit is the LSB of each byte.

Since the CF bit is used in this protocol to indicate the validity of the KPE flag, it may not be used to flag the end of the 8 byte key entry. CF = 1 only as long as KPE is invalid. Therefore, the CPU might not detect that CF = 1 and the key entry is complete before KPE becomes valid. Thus, a counter should be used, as in Figure 4, to flag the end of the new key entry. Then, CF is used to indicate a valid KPE flag.

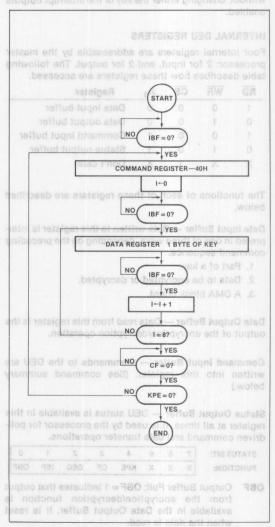

Figure 4. Flowchart for Entering a New Key

decrypting data. The CPU writes 8 data bytes to the DEU's data input buffer for encryption/decryption. CF then goes true (CF = 1) to indicate that the DEU has accepted the 8-byte block. Thus, the CPU may test for IBF = 0 and CF = 1 to terminate the input mode, or it may use a software counter. When the encryption/decryption is complete, the CCMP and OAV interrupts are asserted and the OBF flag is set true (OBF = 1). OAV and OBF are set false again after each of the converted data bytes is read back by the CPU. The CCMP interrupt is set false, and remains false, after the first read. After 8 bytes have been read back by the CPU, CF goes false (CF = 0). Thus, the CPU may test for CF = 0 to terminate the read mode. Also, the CCMP interrupt may be used to initiate a service routine which performs the next series of 8 data reads and 8 data writes. It beldene nismen

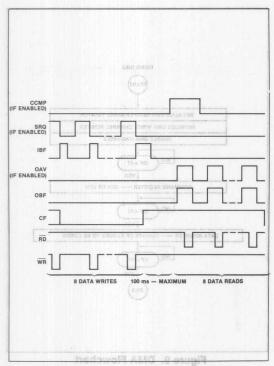

Figure 5. Encrypting/Decrypting Data

SINGLE BYTE COMMANOS

Figure 6 offers two flowcharts outlining the alternative means of implementing the data conversion protocol. Either the CF flag or a software counter may be used to end the read and write modes.

SRQ = 1 implies IBF = 0, OAV = 1 implies OBF = 1. This allows interrupt routines to do data transfers without checking status first. However, the OAV service routine must detect and flag the end of a data conversion.

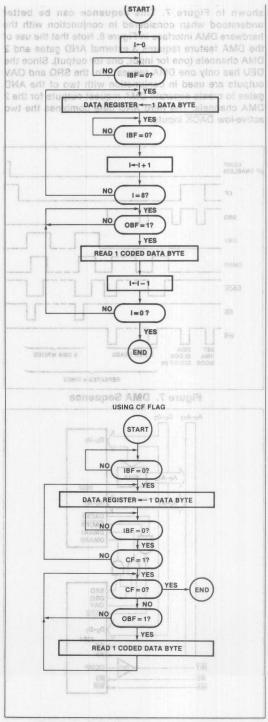

Figure 6. Data Conversion Flowcharts

#### **USING DMA**

The timing sequence for data conversions using DMA is shown in Figure 7. This sequence can be better understood when considered in conjunction with the hardware DMA interface in Figure 8. Note that the use of the DMA feature requires 3 external AND gates and 2 DMA channels (one for input, one for output). Since the DEU has only one DMA request pin, the SRQ and OAV outputs are used in conjunction with two of the AND gates to create separate DMA request outputs for the 2 DMA channels. The third AND gate combines the two active-low DACK inputs.

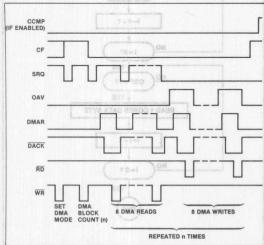

Figure 7. DMA Sequence

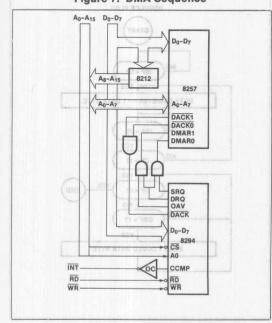

Figure 8. DMA Interface

To initiate a DMA transfer, the CPU must first initialize the two DMA channels as shown in the flowchart in Figure 9. It must then issue a Set Mode command to the DEU enabling the OAV, SRQ, and DMA outputs. The CCMP interrupt may be enabled or disabled, depending on whether that output is desired. Following the Set Mode command, there must be a data byte giving the number of 8-byte blocks of data (n<256) to be converted. The DEU then generates the required number of DMA requests to the 2 DMA channels with no further CPU intervention. When the requested number of blocks has been converted, the DEU will set CF and assert the CCMP interrupt (if enabled). CCMP then goes false again with the next write to the DEU (command or data). Upon completion of the conversion, the DMA mode is disabled and the DEU returns to the encrypt/decrypt mode. The enabled interrupt outputs, however, will remain enabled until another Set Mode command is issued.

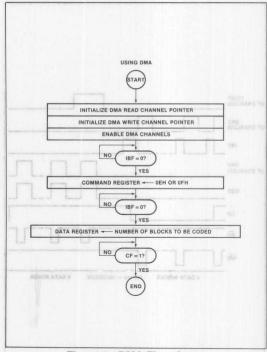

Figure 9. DMA Flowchart

# SINGLE BYTE COMMANDS

Figure 10 shows the timing and protocol for single byte commands. Note that any of the commands is effective as a pacify command in that they may be entered at any time, except during a DMA conversion. The DEU is thus set to a known state. However, if a command is issued out of sequence, an additional protocol is required (Figure 11). The CPU must wait until the command is accepted (IBF = 0). A data read must then be issued to clear anything the preceding command sequence may have left in the Data Output Buffer.

# CPUIDEU INTERFACES

Figures 12 through 15 illustrate four interface configurations used in the CPU/DEU data transfers. In all cases SRQ will be true (if enabled) and IBF will be false when the DEU is ready to accept data or commands.

# OSCILLATOR AND TIMING CIRCUITS

The 8294's internal timing generation is controlled by a self-contained oscillator and timing circuit. A choice of crystal, L-C or external clock can be used to derive the basic oscillator frequency.

The resident timing circuit consists of an oscillator, a state counter and a cycle counter as illustrated in Figure 16.

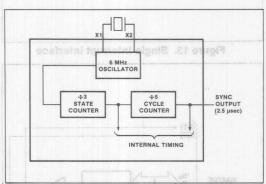

Figure 16. Oscillator Configuration

# **OSCILLATOR**

The on-board oscillator is a series resonant circuit with a frequency range of 1 to 6 MHz. Pins X1 and X2 are input and output (respectively) of a high gain amplifier stage. A crystal or inductor and capacitator connected between X1 and X2 provide the feedback and proper phase shift for oscillation. Recommended connections for crystal or L-C are shown in Figure 17.

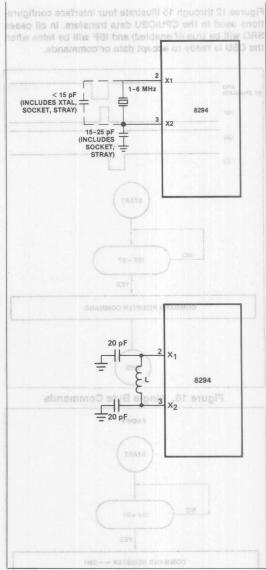

Figure 17. Recommended Crystal and L-C Connections

A recommended range of inductance and capacitance combinations is given below:

L =  $120 \mu$ H corresponds to 3 MHz L =  $45 \mu$ H corresponds to 5 MHz

An external clock signal can also be used as a frequency reference to the 8294; however, the levels are *not* compatible. The signal must be in the 1 MHz-6 MHz frequency range and must be connected to pins X1 and X2 by buffers with a suitable pull-up resistor to guarantee that a logic "1" is above 3.8 volts. The recommended connection is shown in Figure 18.

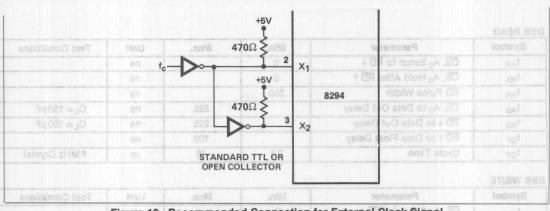

Figure 18. Recommended Connection for External Clock Signal

- 2 General Purpose Outputs

The Intel® 8295 Dot Matrix Printer Controller provides an interface for microprocessors to the LRC 7040 Series dot matrix impact printers. It may also be used as an interface to other similar printers.

The chip may be used in a serial or parallel communication mode with the host processor. In parallel mode, data transfers are based on polling, interrupts, or DMA. Furthermore, it provides internal buffering of up to 40 characters and contains a  $7 \times 7$  matrix character generator accommodating 64 ASCII characters.

# **FUNCTIONAL DESCRIPTION**

The 8295 interfaces microcomputers to the LRC 7040 Series dot matrix impact printers, and to other similar printers. It provides internal buffering of up to 40 characters. Printing begins automatically when the buffer is full or when a carriage return character is received. It provides a modified 7x7 matrix character generator. The character set includes 64 ASCII characters.

Communication between the 8295 and the host processor can be implemented in either a serial or parallel mode. The parallel mode allows for character transfers into the buffer via DMA cycles. The serial mode features selectable data rates from 110 to 4800 baud.

The 8295 also offers two general purpose output pins which can be set or cleared by the host processor. They can be used with various printers to implement such functions as ribbon color selection, enabling form release solenoid, and reverse document feed.

# COMMAND SUMMARY

COMMINIA	IND GOIMMAITI
Hex Code	Description
one oo rese	Set GP1. This command brings the GP1 pin to a logic high state. After power on it is automatically set high.
01	Set GP2. Same as the above but for GP2.
02	Clear GP1. Sets GP1 pin to logic low state, inverse of command 00.
03	Clear GP2. Same as above but for GP2. Inverse command 01.
04	Software Reset. This is a pacify command. This command is not effective immediately after commands requiring a parameter, as the Reset command will be interpreted as a parameter.
05	Print 10 characters/in. density.
06	Print 12 characters/in. density.
_ v07 y yus	Print double width characters. This command prints characters at twice the normal width, that is, at either 17 or 20 characters per line.
08 besu sugari Tod of the	Enable DMA mode; must be followed by two bytes specifying the number of data characters to be fetched. Least significant byte accepted first.

Hex Code	Description
09	Tab character.
0A	Line feed.
OB ed	Multiple Line Feed; must be followed by a byte specifying the number of line feeds.
0C	Top of Form. Enables the line feed output until the Top of Form input is activated.
OD	Carriage Return. Signifies end of a line and enables the printer to start printing.
0E	Set Tab #1, followed by tab position byte.
0F	Set Tab #2, followed by tab position byte Should be greater than Tab #1.
10	Set Tab #3, followed by tab position byte. Should be greater than Tab #2.
land-petible end not recease of ni recease o	Print Head Home on Right. On some printers the print head home position is on the right. This command would enable normal left to right printing with such printers.
12	Set Strobe Width; must be followed by strobe width selection byte. This command adjusts the duration of the strobe activa-

# PROGRAMMABLE PRINTING OPTIONS

# CHARACTER DENSITY

The character density is programmable at 10 or 12 characters/inch (32 or 40 characters/line). The 8295 is automatically set to 12 characters/inch at power-up. Invoking the Print Double-Width command halves the character density (5 or 6 characters/inch). The 10 char/in or 12 char/in command must be re-issued to cancel the Double-Width mode. Different character density modes may not be mixed within a single line of printing.

#### **PRINT INTENSITY**

The intensity of the printed characters is determined by the amount of time during which the solenoid is on. This on-time is programmable via the Set Strobe-Width command. A byte following this command sets the solenoid on-time according to Table 2. Note that only the three least significant bits of this byte are important.

Table 2. Solenoid On-Time

D7—D3	D2	D1	D0	Solenoid On (microsec)
х	0	0	0	200
X	0	0	1	240
×	0	1	0	280
X	0	1	1	320
X	1	0	0	360
X	1	0	1	400
X	1	1	0	440
×	1	1	1	480

# **TABULATIONS**

Up to three tabulation positions may be specified with the 8295. The column position of each tabulation is selected by issuing the Set Tab commands, each fol-

lowed by a byte specifying the column. The tab positions will then remain valid until new Set Tab commands are issued.

Sending a tab character (09H) will automatically fill the character buffer with blanks up to the next tab position. The character sent immediately after the tab character will thus be stored and printed at that position.

# **CPU TO 8295 INTERFACE**

Communication between the CPU and the 8295 may take place in either a serial or parallel mode. However, the selection of modes is inherent in the system hardware; it is not software programmable. Thus, the two modes cannot be mixed in a single 8295 application.

# PARALLEL INTERFACE

Two internal registers on the 8295 are addressable by the CPU: one for input, one for output. The following table describes how these registers are accessed.

RD	WR	CS	Register & war
1	0	0	Input Data Register
0	odio	0	Output Status Register

Input Data Register—Data written to this register is interpreted in one of two ways, depending on how the data is coded.

- 1. A command to be executed (0XH or 1XH).
- A character to be stored in the character buffer for printing (2XH, 3XH, 4XH, or 5XH). See the character set. Table 2.

Output Status Register—8295 status is available in this register at all times.

STATUS BIT:	7	6	5	4	3	2	-1	0
FUNCTION:	X	X	PA	DE	X	х	IBF	X

PA—Parameter Required; PA = 1 indicates that a command requiring a parameter has been received. After the necessary parameters have been received by the 8295, the PA flag is cleared.

**DE**—DMA Enabled; DE = 1 whenever the 8295 is in DMA mode. Upon completion of the required DMA transfers, the DE flag is cleared.

IBF—Input Buffer Full; IBF = 1 whenever data is written to the Input Data Register. No data should be written to the 8295 when IBF = 1.

A flow chart describing communication with the 8295 is shown in Figure 3.

The interrupt request output (IRQ, Pin 36) is available on the 8295 for interrupt driven systems. This output is asserted true whenever the 8295 is ready to receive data.

To improve bus efficiency and CPU overhead, data may be transferred from main memory to the 8295 via DMA cycles. Sending the Enable DMA command (08H) activates the DMA channel of the 8295. This command must be followed by two bytes specifying the length of the data string to be transferred (least significant byte first). The 8295 will then assert the required DMA requests to

the 8257 DMA controller without further CPU intervention. Figure 4 shows a block diagram of the 8295 in DMA mode.

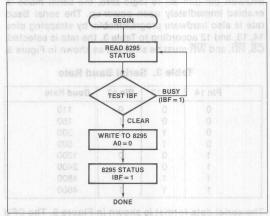

Figure 3. Host to 8295 Protocol Flowchart

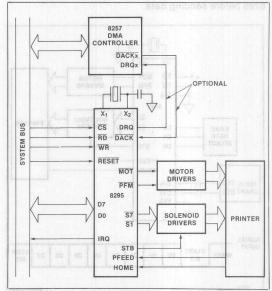

Figure 4. Parallel System Interface

Data transferred in the DMA mode may be either commands or characters or a mixture of both. The procedure is as follows:

- Set up the 8257 DMA controller channel by sending a starting address and a block length.
- Set up the 8295 by issuing the "Enable DMA" command (08H) followed by two bytes specifying the block length (least significant byte first).

The DMA enabled flag (DE) will be true until the assigned data transfer is completed. Upon completion of the transfer, the flag is cleared and the interrupt request (IRQ) signal is asserted. The 8295 then returns to the non-DMA mode of operation.

#### SERIAL INTERFACE Monthly relicatings AMG VSSB entr

The 8295 may be hardware programmed to operate in a serial mode of communication. By connecting the IRQ/SER pin (pin 36) to logic zero, the serial mode is enabled immediately upon power-up. The serial Baud rate is also hardware programmable; by strapping pins 14, 13, and 12 according to Table 3, the rate is selected. CS, RD, and WR must be strapped as shown in Figure 5.

**Table 3. Serial Baud Rate** 

Pin 14	Pin 13	Pin 12	Baud Rate
0	0	0	110
0	0 =	a.io 1	150
0	1 1 7 7	0	300
0	1	0 = 10	600
1	0	0	1200
1	0	UTATE SESS	2400
1	1	0	4800
1	1	1	4800

The serial data format is shown in Figure 5. The CPU should wait for a clear to send signal (CTS) from the 8295 before sending data.

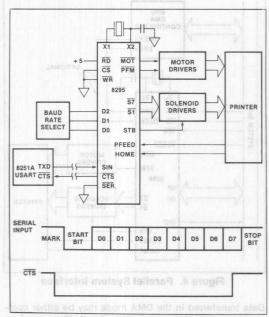

Figure 5. Serial Interface to UART (8251A)

# 8295 TO PRINTER INTERFACE

The strobe output signal of the 8295 determines the duration of the solenoid outputs, which hold the data to the printer. These solenoid outputs cannot drive the printer solenoids directly. They should be buffered through solenoid drivers as shown in Figure 6. Recommended solenoid and motor driver circuits may be found in the printer manufacturer's interface guide.

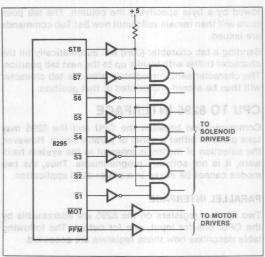

Figure 6. 8295 To Printer Solenoid Interface

# OSCILLATOR AND TIMING CIRCUITS

The 8295's internal timing generation is controlled by a self-contained oscillator and timing circuit. A 6 MHz crystal is used to derive the basic oscillator frequency. The resident timing circuit consists of an oscillator, a state counter and a cycle counter as illustrated in Figure 7. The recommended crystal connection is shown in Figure 8.

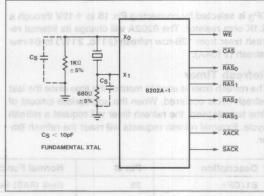

Figure 3. Crystal Operation for the 8202A-1

### **Functional Description**

The 8202A provides a complete dynamic RAM controller for microprocessor systems as well as expansion memory boards. All of the necessary control signals are provided for 2104A, 2117, and 2118 dynamic RAM's.

All 8202A timing is generated from a single reference clock. This clock is provided via an external oscillator or an on chip crystal oscillator. All output signal transitions are synchronous with respect to this clock reference, except for the CPU handshake signals SACK and XACK (trailing edge).

CPU memory requests normally use the RD and WR inputs. The advanced READ mode allows ALE and S1 to be used in place of the RD input.

Failsafe refresh is provided via an internal refresh timer which generates internal refresh requests. Refresh requests can also be generated via the REFRQ input.

An on-chip synchronizer/arbiter prevents memory and refresh requests from affecting a cycle in progress. The READ, WRITE, and external REFRESH requests may be asynchronous to the 8202A clock; on-chip logic will synchronize the requests, and the arbiter will decide if the requests should be delayed, pending completion of a cycle in progress.

#### Option Selection

The 8202A has three strapping options. When  $OP_1$  is selected (16K mode only), pin 32 changes from a  $\overline{RD}$  input to an S1 input, and pin 34 changes from a REFREQ input to an ALE input. See "Refresh Cycles" and "Read Cycles" for more detail.  $OP_1$  is selected by tying pin 25 to  $\pm$ 12V though a 5.1K ohm resistor.

When  $OP_2$  is selected, by connecting pin 36 to  $\pm 12V$  through a 1K ohm resistor, pin 37 changes from a crystal input (X<sub>1</sub>) to the CLK input for an external TTL clock.

OP<sub>3</sub> is selected by connecting Pin 18 to +12V through a 5.1K ohm resistor. The 8202A will change its internal refresh timer from 128-row refresh (2118, 2117) to 64-row refresh (2104A).

#### **Refresh Timer**

The refresh timer is used to monitor the time since the last refresh cycle occurred. When the appropriate amount of time has elapsed, the refresh timer will request a refresh cycle. External refresh requests will reset the refresh timer.

#### **Refresh Counter**

The refresh counter is used to sequentially refresh all of the memory's rows. The 8-bit counter is incremented after every refresh cycle.

## **Address Multiplexer**

The address multiplexer takes the address inputs and the refresh counter outputs, and gates them onto the address outputs at the appropriate time. The address outputs, in conjunction with the RAS and CAS outputs, determine the address used by the dynamic RAMs for read, write, and refresh cycles. During the first part of a read or write cycle, ALO-AL6 are gated to OUTO-OUT6, then AHO-AH6 are gated to the address outputs.

During a refresh cycle, the refresh counter is gated onto the address outputs. All refresh cycles are RAS-only refresh (CAS inactive, RAS active).

To minimize buffer delay, the information on the address outputs is inverted from that on the address inputs.

OUT<sub>0</sub>-OUT<sub>6</sub> do not need inverters or buffers unless additional drive is required.

## Synchronizer/Arbiter

The 8202A has three inputs, REFRQ/ALE (pin 34), RD (pin 32) and WR (pin 31). The RD and WR inputs allow an external CPU to request a memory read or write cycle, respectively. The REFRQ/ALE allows refresh requests to be requested external to the 8202A.

All three of these inputs may be asynchronous with respect to the 8202A's clock. The arbiter will resolve conflicts between refresh and memory requests, for both pending cycles and cycles in progress. Read and write requests will be given priority over refresh requests.

#### **System Operation**

The 8202A is always in one of the following states:

- a) IDLE
- b) TEST Cycle
- c) REFRESH Cycle
- d) READ Cycle
- e) WRITE Cycle

The 8202A is normally in the IDLE state. Whenever one of the other cycles is requested, the 8202A will leave the IDLE state to perform the desired cycle. If no other cycles are pending, the 8202A will return to the IDLE state.

AL6/OP3	18	Address Input	64-ROW Refresh

Figure 4. 8202A Option Selection

#### Test Cycle Him hemsongo el metava rossecondorolm A

The TEST Cycle is used to check operation of several 8202A internal functions. TEST cycles are requested by activating the RD and WR inputs, independent of PCS. The TEST Cycle will reset the refresh address counter and perform a WRITE Cycle. The TEST Cycle should not be used in normal system operation, since it would affect the dynamic RAM refresh.

## Refresh Cycles ,emit easons been lienevo erit etaluo

The 8202A has two ways of providing dynamic RAM refresh; a "atiny-visa" amoreo ellernon ASOSB erit cont2 emit ent vd atugni stab MARI erit te eldste ed jaum stab erit

- 1) Internal (failsafe) refresh misulant switch 2500 2AO
- en 2) External (hidden) refresh and ton each metave ent

Both types of 8202A refresh cycles activate all of the RAS outputs, while CAS, WE, SACK, and XACK remain inactive.

Internal refresh is generated by the on-chip refresh timer. The timer uses the 8202A clock to ensure that refresh of all rows of the dynamic RAM occurs every 2 milliseconds. If REFRQ is inactive, the refresh timer will request a refresh cycle every 10-16 microseconds.

External refresh is requested via the REFRQ input (pin 34). External refresh control is not available when the Advanced-Read mode is selected. External refresh requests are latched, then synchronized to the 8202A clock.

The arbiter will allow the refresh request to start a refresh cycle only if the 8202A is not in the middle of a cycle.

Simultaneous memory request and external refresh request will result in the memory request being honored first. This 8202A characteristic can be used to "hide" refresh cycles during system operation. A circuit similar to Figure 5 can be used to decode the CPU's instruction fetch status to generate an external refresh request. The refresh request is latched while the 8202A performs the instruction fetch; the refresh cycle will start immediately after the memory cycle is completed, even if the RD input has not gone inactive. If the CPU's instruction decode time is long enough, the 8202A can complete the refresh cycle before the next memory request is generated.

Certain system configurations require complete external refresh requests. If external refresh is requested faster than the minimum internal refresh timer (tREF), then, in effect, all refresh cycles will be caused by the external refresh request, and the internal refresh timer will never generate a refresh request.

Figure 7. Read Access Time

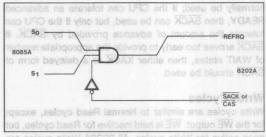

Figure 5. Hidden Refresh

## **Read Cycles**

The 8202A can accept two different types of memory Read requests:

- 1) Normal Read, via the RD input
- 2) Advanced Read, using the S1 and ALE inputs

The user can select the desired Read request configuration via the B1/OP1 hardware strapping option on pin 25.

	Normal Read	Advanced Read
Pin 25	B1 input	+12 Volt Option
Pin 32	RD input	S1 input
Pin 34	REFRQ input	ALE input
# RAM banks	4 (RAS 0-3)	2 (RAS 2-3)
Ext. Refresh	Yes	No

Figure 6. 8202A Read Options

Normal Reads are requested by activating the RD input, and keeping it active until the 8202A responds with an XACK pulse. The RD input can go inactive as soon as the command hold time (tCHS) is met.

Advanced Read cycles are requested by pulsing ALE while S1 is active; if S1 is inactive (low) ALE is ignored. Advanced Read timing is similiar to Normal Read timing, except the falling edge of ALE is used as the cycle start reference.

If a Read cycle is requested while a refresh cycle is in progress, then the 8202A will set the internal delayed-SACK latch. When the Read cycle is eventually started, the 8202A will delay the active SACK transition until XACK goes active, as shown in the AC timing diagrams. This delay was designed to compensate for the CPU's READY setup and hold times. The delayed–SACK latch is cleared after every READ cycle.

Based on system requirements, either SACK or XACK can be used to generate the CPU READY signal. XACK will

normally be used; if the CPU can tolerate an advanced READY, then SACK can be used, but only if the CPU can tolerate the amount of advance provided by SACK. If SACK arrives too early to provide the appropriate number of WAIT states, then either XACK or a delayed form of SACK should be used.

#### Write Cycles

Write cycles are similiar to Normal Read cycles, except for the WE output. WE is held inactive for Read cycles, but goes active for Write cycles. All 8202A Write cycles are "early-write" cycles; WE goes active before CAS goes active by an amount of time sufficient to keep the dynamic RAM output buffers turned off.

### **General System Considerations**

All memory requests (Normal Reads, Advanced Reads, Writes) are qualified by the PCS input. PCS should be stable, either active or inactive, prior to the leading edge of RD, WR, or ALE. Systems which use battery backup should pullup PCS to prevent erroneous memory requests, and should also pullup WR to keep the 8202A out of its test mode.

In order to minimize propagation delay, the 8202A uses an inverting address multiplexer without latches. The system must provide adequate address setup and hold times to guarantee RAS and CAS setup and hold times for the RAM. The 8202A tad AC parameter should be used for this system calculation.

The B0-B1 inputs are similar to the address inputs in that they are not latched. B0 and B1 should not be changed during a memory cycle, since they directly control which RAS output is activated.

The 8202A uses a two-stage synchronizer for the memory request inputs (RD, WR, ALE), and a separate two stage synchronizer for the external refresh input (REFRQ). As with any synchronizer, there is always a finite probability of metastable states inducing system errors. The 8202A synchronizer was designed to have a system error rate less than 1 memory cycle every three years based on the full operating range of the 8202A.

the 8202A will delay the active SACK transition until XACK goes active, as shown in the AC fiming diagrams. This delay was designed to compensate for the CPU's READY setup and hold times. The delayed–SACK letch is cleared

Based on system requirements, either SACK or XACK can be used to generate the OPU READY signal. XACK will

A microprocessor system is concerned with the time data is valid after  $\overline{\text{RD}}$  goes low. See Figure 7. In order to calculate memory read access times, the dynamic RAM's A.C. specifications must be examined, especially the RAS-access time (tRAC) and the CAS-access time (tCAC). Most configurations will be CAS-access limited; i.e., the data from the RAM will be stable t<sub>CC,max</sub> (8202A) + tCAC (RAM) after a memory read cycle is started. Be sure to add any delays (due to buffers, data latches, etc.) to calculate the overall read access time.

Since the 8202A normally performs "early-write" cycles, the data must be stable at the RAM data inputs by the time  $\overline{\text{CAS}}$  goes active, including the RAM's data setup time. If the system does not normally guarantee sufficient write data setup, you must either delay the  $\overline{\text{WR}}$  input signal or delay the 8202A  $\overline{\text{WE}}$  output.

Delaying the WR input will delay all 8202A timing, including the READY handshake signals, SACK and XACK, which may increase the number of WAIT states generated by the CPU.

If the WE output is externally delayed beyond the CAS active transition, then the RAM will use the falling edge of WE to strobe the write data into the RAM. This WE transition should not occur too late during the CAS active transition, or else the WE to CAS requirements of the RAM will not be met.

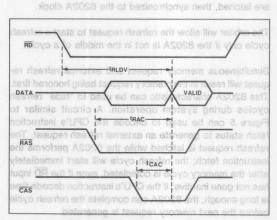

Figure 7. Read Access Time

refresh requests. If external refresh is requested faster than the minimum internal refresh timer (type), then, in effect, all refresh cycles will be caused by the external re-

fresh request, and the internal refresh timer will never

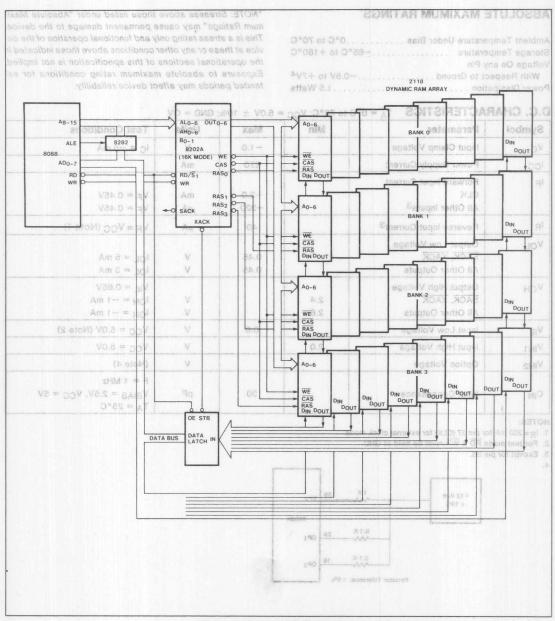

Figure 8. Typical 8088 System

### **ABSOLUTE MAXIMUM RATINGS'**

 \*NOTE: Stresses above those listed under "Absolute Maximum Ratings" may cause permanent damage to the device. This is a stress rating only and functional operation of the device at these or any other conditions above those indicated in the operational sections of this specification is not implied. Exposure to absolute maximum rating conditions for extended periods may affect device reliability.

WE	C <sub>L</sub> = 224 pF
CAS	C <sub>I</sub> = 320 pF

#### NOTEC

- t<sub>SC</sub> is a reference point only. ALE, RD, WR, and REFRQ inputs do not have to be externally synchronized to 8202A clock.
- If t<sub>RS</sub> min and t<sub>MRS</sub> min are met then, t<sub>CA</sub>, t<sub>CR</sub>, and t<sub>CC</sub> are valid, otherwise t<sub>CS</sub> is valid.
- †ASR, †RAH, †ASC, †CAH, and †RSH depend upon B0-B1 and CPU address remaining stable throughout the memory cycle. The address inputs are not latched by the 8202A.
- 4. For back-to-back refresh cycles, tRC max = 13tp
- t<sub>RC</sub> max is valid only if t<sub>RMP</sub> min is met (READ, WRITE followed by REFRESH) or t<sub>MRP</sub> min is met (REFRESH followed by READ, WRITE).
- 6. tRFR is valid only if tRS min and tRMS min are met.
- 7. t<sub>XW</sub> min applies when RD, WR has already gone high. Otherwise XACK follows RD. WR.
- WE goes high according to twch or tww, whichever occurs first.

Use the Test Load as the base capacitance for estimating filming shifts for extent critical liming parameters.

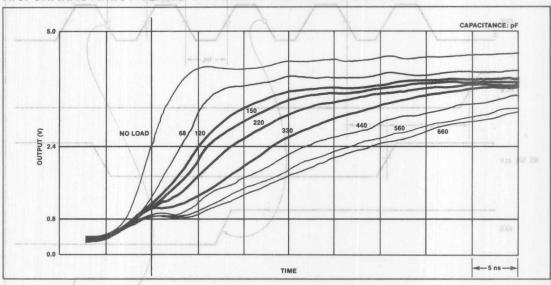

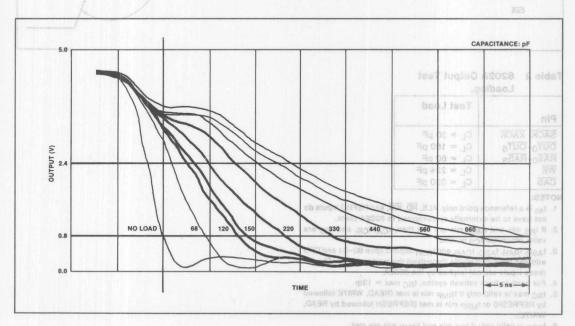

The typical rising and falling characteristic curves can be used to determine the effects of capacitive loading on the A.C. Timing Parameters. Using this

design tool in conjunction with the timing waveforms, the designer can determine typical timing shifts based on system capacitive load.

## A.C. CHARACTERISTICS FOR DIFFERENT CAPACITIVE LOADS

#### NOTE:

Use the Test Load as the base capacitance for estimating timing shifts for system critical timing parameters.

#### TYPICAL CONDITIONS:

 $T_A = 25^{\circ}C$  Pins not under test are loaded with Test Load  $V_{CC} = +5V$  capacitance.  $t_p = 50 \text{ ns}$ 

Example: Find the effect on t<sub>CR</sub> and t<sub>CC</sub> using 64 22. From the waveform diagrams, we determine that 2118 Dynamic RAMs configured in 4 banks.

- 1. Determine the typical RAS and CAS capacitance:
  From the data sheet RAS = 4 pF and CAS = 4 pF.

  ∴ RAS load = 64 pF + board capacitance.
  CAS load = 256 pF + board capacitance.
  Assume 2 pF/in (trace length) for board capacitance.

## Functional Description Public 2AR own and to lea

The 8203 provides a complete dynamic RAM controller for microprocessor systems as well as expansion memory boards. All of the necessary control signals are provided for 2164, 2118, 2117, and 2104A dynamic RAM's.

The 8203 has three modes, one for 4K dynamic RAM's, one for 16K's and one for 64K's, controlled by pin 35 and pin 18.

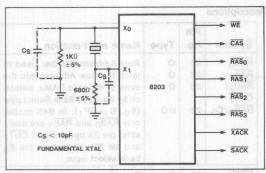

Figure 3. Crystal Operation

All 8203 timing is generated from a single reference clock. This clock is provided via an external oscillator or an on-chip crystal oscillator. All output signal transitions are synchronous with respect to this clock reference, except for the CPU handshake signals SACK and XACK.

CPU memory requests normally use the  $\overline{RD}$  and  $\overline{WR}$  inputs. The Advanced-Read mode allows ALE and S1 to be used in place of the  $\overline{RD}$  input.

Failsafe refresh is provided via an internal timer which generates refresh requests. Refresh requests can also be generated via the REFRQ input.

An on-chip synchronizer/arbiter prevents memory and refresh requests from affecting a cycle in progress. The READ, WRITE, and external REFRESH requests may be asynchronous to the 8203 clock; on-chip logic will synchronize the requests, and the arbiter will decide if the requests should be delayed, pending completion of a cycle in progress.

#### 16K/64K Option Selection

Pin 35 is a strap input that controls the two 8203 modes. Figure 4 shows the four pins that are multiplexed. In 16K mode (pin 35 tied to V<sub>CC</sub> or left open), the 8203 has two Bank Select inputs to select one of four RAS outputs. In this mode, the 8203 is exactly compatible with the Intel 8202A Dynamic RAM Controller. In 64K mode (pin 35 tied to GND), there is only one Bank Select input (pin 26) to select the two RAS outputs. More than two banks of 64K dynamic RAM's can be used with external logic.

#### **Other Option Selections**

The 8203 has three strapping options. When  $OP_1$  is selected (16K mode only), pin 32 changes from a  $\overline{RD}$  input to an S1 input, and pin 34 changes from a REFRQ input to an ALE input. See "Refresh Cycles" and "Read Cycles" for more detail.  $OP_1$  is selected by tying pin 25 to  $\pm$ 12V through a 5.1K ohm resistor.

When  $OP_2$  is selected, by connecting pin 36 to  $V_{CC}$ , pin 37 changes from a crystal input (X<sub>1</sub>) to the CLK input for an external TTL clock.

OP3 is selected by connecting pin 18 to +12V through a 5.1K ohm resistor, the 8203 will change its internal refresh timer from 128-row refresh (2164, 2118, 2117) to 64-row refresh (2104A).

#### **Refresh Timer**

The refresh timer is used to monitor the time since the last refresh cycle occurred. When the appropriate amount of time has elapsed, the refresh timer will request a refresh cycle. External refresh requests will reset the refresh timer.

#### **Refresh Counter**

The refresh counter is used to sequentially refresh all of the memory's rows. The 8-bit counter is incremented after every refresh cycle.

Figure 6. 8203 Option Selection

## Address Multiplexer and material latenage

The address multiplexer takes the address inputs and the refresh counter outputs, and gates them onto the address outputs at the appropriate time. The address outputs, in conjunction with the  $\overline{\text{RAS}}$  and  $\overline{\text{CAS}}$  outputs, determine the address used by the dynamic RAMs for read, write, and refresh cycles. During the first part of a read or write cycle, AL<sub>O</sub>-AL<sub>7</sub> are gated to  $\overline{\text{OUT}}_0-\overline{\text{OUT}}_7$ , then AH<sub>O</sub>-AH<sub>7</sub> are gated to the address outputs.

During a refresh cycle, the refresh counter is gated onto the address outputs. All refresh cycles are RAS-only refresh (CAS inactive, RAS active).

To minimize buffer delay, the information on the address outputs is inverted from that on the address inputs,

OUT<sub>0</sub>-OUT<sub>7</sub> do not need inverters or buffers unless additional drive is required.

## Synchronizer/Arbiter

The 8203 has three inputs, REFRQ/ALE (pin 34),  $\overline{RD}$  (pin 32) and  $\overline{WR}$  (pin 31). The  $\overline{RD}$  and  $\overline{WR}$  inputs allow an external CPU to request a memory read or write cycle, respectively. The REFRQ/ALE allows refresh requests to be requested external to the 8203.

All three of these inputs may be asynchronous with respect to the 8203's clock. The arbiter will resolve conflicts between refresh and memory requests, for both pending cycles and cycles in progress. Read and write requests will be given priority over refresh requests.

#### System Operation

The 8203 is always in one of the following states:

- a) IDLE
- b) TEST Cycle
- c) REFRESH Cycle
- d) READ Cycle in MARI only to second address and form at a body
- e) WRITE Cycle

The 8203 is normally in the IDLE state. Whenever one of the other cycles is requested, the 8203 will leave the IDLE state to perform the desired cycle. If no other cycles are pending, the 8203 will return to the IDLE state.

#### **Test Cycle**

The TEST Cycle is used to check operation of several 8203 internal functions. TEST cycles are requested by activating the  $\overline{PCS}$ ,  $\overline{RD}$  and  $\overline{WR}$  inputs. The TEST Cycle will reset the refresh address counter and perform a WRITE Cycle. The TEST Cycle should not be used in normal system operation, since it would affect the dynamic RAM refresh.

#### **Refresh Cycles**

The 8203 has two ways of providing dynamic RAM refresh:

- 1) Internal (failsafe) refresh
- 2) External (hidden) refresh had become the

Both types of 8203 refresh cycles activate all of the  $\overline{RAS}$  outputs, while  $\overline{CAS}$ ,  $\overline{WE}$ ,  $\overline{SACK}$ , and  $\overline{XACK}$  remain inactive.

Internal refresh is generated by the on-chip refresh timer. The timer uses the 8203 clock to ensure that refresh of all rows of the dynamic RAM occurs every 2 milliseconds (128 cycles) or every 4 milliseconds (256 cycles). If REFRQ is inactive, the refresh timer will request a refresh cycle every 10-16 microseconds.

External refresh is requested via the REFRQ input (pin 34). External refresh control is not available when the Advanced-Read mode is selected. External refresh requests are latched, then synchronized to the 8203 clock.

The arbiter will allow the refresh request to start a refresh cycle only if the 8203 is not in the middle of a cycle.

Simultaneous memory request and external refresh request will result in the memory request being honored first. This 8203 characteristic can be used to "hide" refresh cycles during system operation. A circuit similar to Figure 7 can be used to decode the CPU's instruction fetch status to generate an external refresh request. The refresh request is latched while the 8203 performs the instruction fetch; the refresh cycle will start immediately after the memory cycle is completed, even if the  $\overline{\rm RD}$  input has not gone inactive. If the CPU's instruction decode time is long enough, the 8203 can complete the refresh cycle before the next memory request is generated.

Certain system configurations require complete external refresh requests. If external refresh is requested faster than the minimum internal refresh timer (tREF), then, in effect, all refresh cycles will be caused by the external refresh request, and the internal refresh timer will never generate a refresh request.

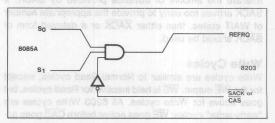

Figure 7. Hidden Refresh

### **Read Cycles**

The 8203 can accept two different types of memory Read requests:

- 1) Normal Read, via the RD input sells?) lement (f
- Advanced Read, using the S1 and ALE inputs (16K mode only)

The user can select the desired Read request configuration via the B1/OP1 hardware strapping option on pin 25.

s to deeden tadt s	Normal Read	Advanced Read
Pin 25	B1 input	+12 Volt Option
Pin 32	RD input	S1 input
Pin 34	REFRQ input	ALE input
# RAM banks	4 (RAS 0-3)	2 (RAS 2-3)
Ext. Refresh	Yes	No

Figure 8. 8203 Read Options

Normal Reads are requested by activating the  $\overline{\text{RD}}$  input, and keeping it active until the 8203 responds with an  $\overline{\text{XACK}}$  pulse. The  $\overline{\text{RD}}$  input can go inactive as soon as the command hold time (tCHS) is met.

Advanced Read cycles are requested by pulsing ALE while S1 is active; if S1 is inactive (low) ALE is ignored. Advanced Read timing is similiar to Normal Read timing, except the falling edge of ALE is used as the cycle start reference.

If a Read cycle is requested while a refresh cycle is in progress, then the 8203 will set the internal delayed-SACK latch. When the Read cycle is eventually started, the 8203 will delay the active SACK transition until XACK goes active, as shown in the AC timing diagrams. This delay was designed to compensate for the CPU's READY setup and hold times. The delayed–SACK latch is cleared after every READ cycle.

Based on system requirements, either SACK or XACK can be used to generate the CPU READY signal. XACK will normally be used; if the CPU can tolerate an advanced READY, then SACK can be used, but only if the CPU can tolerate the amount of advance provided by SACK. If SACK arrives too early to provide the appropriate number of WAIT states, then either XACK or a delayed form of SACK should be used.

#### Write Cycles

Write cycles are similiar to Normal Read cycles, except for the  $\overline{WE}$  output.  $\overline{WE}$  is held inactive for Read cycles, but goes active for Write cycles. All 8203 Write cycles are "early-write" cycles;  $\overline{WE}$  goes active before  $\overline{CAS}$  goes active by an amount of time sufficient to keep the dynamic RAM output buffers turned off.

## General System Considerations

All memory requests (Normal Reads, Advanced Reads, Writes) are qualified by the PCS input. PCS should be stable, either active or inactive, prior to the leading edge of RD, WR, or ALE. Systems which use battery backup should pullup PCS to prevent erroneous memory requests.

In order to minimize propagation delay, the 8203 uses an inverting address multiplexer without latches. The system must provide adequate address setup and hold times to guarantee RAS and CAS setup and hold times for the RAM. The tAD AC parameter should be used for this system calculation.

The B<sub>0</sub>-B<sub>1</sub> inputs are similiar to the address inputs in that they are not latched. B<sub>0</sub> and B<sub>1</sub> should not be changed during a memory cycle, since they directly control which RAS output is activated.

The 8203 uses a two-stage synchronizer for the memory request inputs (RD, WR, ALE), and a separate two stage synchronizer for the external refresh input (REFRQ). As with any synchronizer, there is always a finite probability of metastable states inducing system errors. The 8203 synchronizer was designed to have a system error rate less than 1 memory cycle every three years based on the full operating range of the 8203.

A microprocessor system is concerned when the data is valid after  $\overline{\text{RD}}$  goes low. See Figure 9. In order to calculate memory read access times, the dynamic RAM's A.C. specifications must be examined, especially the RAS-access time (tRAC) and the CAS-access time (tCAC). Most configurations will be CAS-access limited; i.e., the data from the RAM will be stable tcc,max (8203) + tCAC (RAM) after a memory read cycle is started. Be sure to add any delays (due to buffers, data latches, etc.) to calculate the overall read access time.

Since the 8203 normally performs "early-write" cycles, the data must be stable at the RAM data inputs by the time  $\overline{\text{CAS}}$  goes active, including the RAM's data setup time. If the system does not normally guarantee sufficient write data setup, you must either delay the  $\overline{\text{WR}}$  input signal or delay the 8203  $\overline{\text{WE}}$  output.

Delaying the  $\overline{\text{WR}}$  input will delay all 8203 timing, including the READY handshake signals,  $\overline{\text{SACK}}$  and  $\overline{\text{XACK}}$ , which may increase the number of WAIT states generated by the CPU.

If the WE output is externally delayed beyond the CAS active transition, then the RAM will use the falling edge of WE to strobe the write data into the RAM. This WE transition should not occur too late during the CAS active transition, or else the WE to CAS requirements of the RAM will not be met

Use the Test Load as the base capacitance for estimating timing shifts for system critical timing parameters.

#### **TYPICAL CONDITIONS:**

 $T_{A} = 25^{\circ}C$   $V_{CC} = +5V$   $t_{p} = 50 \text{ ns}$ 

Pins not under test are loaded with Test Load capacitance.

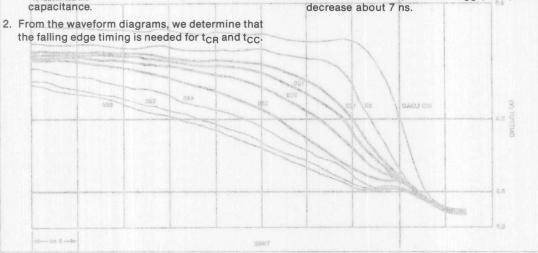

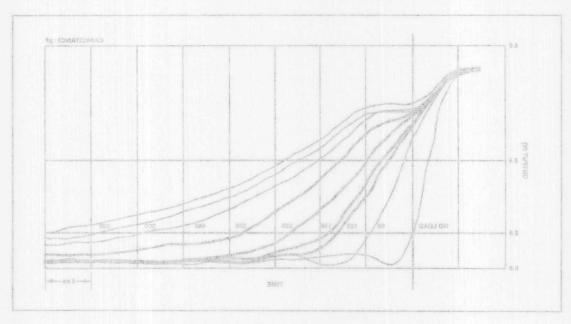

Example: Find the effect on t<sub>CR</sub> and t<sub>CC</sub> using 32 2164 Dynamic RAMs configured in 2 banks.

1. Determine the typical RAS and CAS capacitance: From the data sheet RAS = 5 pF and CAS = 5 pF. CAS load = 160 pF + board capacitance. Assume 2 pF/in (trace length) for board

Next find the curve that best approximates the evil test load; i.e., 68 pF for RAS and 330 pF for CAS.

3. If we use 88 pF for RAS loading, then t<sub>CR</sub> (min.) spec should be increased by about 1 ns, and ton .: RAS load = 80 pF + board capacitance. AGAD IM (max.) spec should be increased by about 2 ns. Similarly if we use 176 pF for CAS, then t<sub>CC</sub> (min.) should decrease by 3 ns and t<sub>CC</sub> (max.) should

 $t_0 = 50 \text{ rm}$ 

shifts for system critical timing parameters.

The HMOS 8206 Error Detection and Correction Unit is a high-speed device that provides error detection and correction for memory systems (static and dynamic) requiring high reliability and performance. Each 8206 handles 8 or 16 data bits and up to 8 check bits. 8206's can be cascaded to provide correction and detection for up to 80 bits of data. Other 8206 features include the ability to handle byte writes, memory initialization, and error logging.

with the proper write check bits on CBO.

The 8206 Error Detection and Correction Unit provides greater memory system reliability through its ability to detect and correct memory errors. It is a single chip device that can detect and correct all single bit errors and detect all double bit and some higher multiple bit errors. Some other odd multiple bit errors (e.g., 5 bits in error) are interpreted as single bit errors, and the CE flag is raised. While some even multiple bit errors (e.g., 4 bits in error) are interpreted as no error, most are detected as double bit errors. This error handling is a function of the number of check bits used by the 8206 (see Figure 2) and the specific Hamming code used. Errors in check bits are not distinguished from errors in a word.

For more information on error correction codes, see Intel Application Notes AP-46 and AP-73.

A single 8206 handles 8 or 16 bits of data, and up to 5 8206's can be cascaded in order to handle data paths of 80 bits. For a single 8206 8 bit system, the DI<sub>8-15</sub>, DO/WDI<sub>8-15</sub> and  $\overline{BM}_1$  inputs are grounded. See the Multi-Chip systems section for information on 24-80 bit systems.

The 8206 has a "flow through" architecture. It supports two kinds of error correction architecture: 1) Flow-through, or correct-always; and 2) Parallel, or check-only. There are two separate 16-pin busses.

one to accept data from the RAM (DI) and the other to deliver corrected data to the system bus (DO/WDI). The logic is entirely combinatorial during a read cycle. This is in contrast to an architecture with only one bus, with bidirectional bus drivers that must first read the data and then be turned around to output the corrected data. The latter architecture typically requires additional hardware (latches and/or transceivers) and may be slower in a system due to timing skews of control signals.

#### **READ CYCLE**

With the R/W pin high, data is received from the RAM outputs into the DI pins where it is optionally latched by the STB signal. Check bits are generated from the data bits and compared to the check bits read from the RAM into the CBI pins. If an error is detected the ERROR flag is activated and the correctable error flag (CE) is used to inform the system whether the error was correctable or not. With the BM inputs high, the word appears corrected at the DO pins if the error was correctable, or unmodified if the error was uncorrectable.

If more than one 8206 is being used, then the check bits are read by the master. The slaves generate a partial parity output (PPO) and pass it to the master. The master 8206 then generates and returns the syndrome to the slaves (SYO) for correction of the data.

The 8206 may alternatively be used in a "check-only" mode with the CRCT pin left high. With the correction facility turned off, the propagation delay from memory outputs to 8206 outputs is significantly shortened. In this mode the 8206 issues an ERROR flag to the CPU, which can then perform one of several options: lengthen the current cycle for correction, restart the instruction, perform a diagnostic routine, etc.

A syndrome word, five to eight bits in length and containing all necessary information about the existence and location of an error, is made available to the system at the SYO<sub>0-7</sub> pins. Error logging may be accomplished by latching the syndrome and the memory address of the word in error.

#### WRITE CYCLE

For a full write, in which an entire word is written to memory, the data is written directly to the RAM, bypassing the 8206. The same data enters the 8206 through the WDI pins where check bits are generated. The Byte Mark inputs must be low to tristate the DO drivers. The check bits, 5 to 8 in number, are then written to the RAM through the CBO pins for storage along with the data word. In a multi-chip system, the master writes the check bits using partial parity information from the slaves.

In a partial write, part of the data word is overwritten, and part is retained in memory. This is accomplished by performing a read-modify-write cycle. The complete old word is read into the 8206 and corrected,

with the syndrome internally latched by R/W going low. Only that part of the word not to be modified is output onto the DO pins, as controlled by the Byte Mark inputs. That portion of the word to be overwritten is supplied by the system bus. The 8206 then calculates check bits for the new word, using the byte from the previous read and the new byte from the system bus, and writes them to the memory.

### **READ-MODIFY-WRITE CYCLES**

On the high-to-low

Upon detection of an error the 8206 may be used to correct the bit in error in memory. This reduces the probability of getting multiple-bit errors in subsequent read cycles. This correction is handled by executing read-modify-write cycles.

The read-modify-write cycle is controlled by the R/W input. After (during) the read cycle, the system dynamic RAM controller or CPU examines the 8206 ERROR and CE outputs to determine if a correctable error occurred. If it did, the dynamic RAM controller or CPU forces R/W low, telling the 8206 to latch the generated syndrome and drive the corrected check bits onto the CBO outputs. The corrected data is available on the DO pins. The DRAM controller then writes the corrected data and corresponding check bits into memory.

The 8206 may be used to perform read-modify-writes in one or two RAM cycles. If it is done in two cycles, the 8206 latches are used to hold the data and check bits from the read cycle to be used in the following write cycle. The Intel 8207 Advanced Dynamic RAM controller allows read-modify-write cycles in one memory cycle. See the System Environment section.

#### INITIALIZATION

A memory system operating with ECC requires some form of initialization at system power-up in order to set valid data and check bit information in memory. The 8206 supports memory initialization by the write zero function. By activating the  $\overline{WZ}$  pin, the 8206 will write a data pattern of zeros and the associated check bits in the current write cycle. By thus writing to all memory at power-up, a controller can set memory to valid data and check bits. Massive memory failure, as signified by both data and check bits all ones or zeros, will be detected as an uncorrectable error.

#### **MULTI-CHIP SYSTEMS**

A single 8206 handles 8 or 16 bits of data and 5 or 6 check bits, respectively. Up to 5 8206's can be cascaded for 80 bit memories with 8 check bits.

When cascaded, one 8206 operates as a master, and all others as slaves. As an example, during a read cycle in a 32 bit system with one master and one slave, the slave calculates parity on its portion of the word—"partial parity"—and presents it to the master through the PPO pins. The master combines the partial parity from the slave with the parity it calculated from its own portion of the word to generate

the syndrome. The syndrome is then returned by the master to the slave for error correction. In systems of data and 5 or 6 with more than one slave the above description continues to apply, except that the partial parity outputs of the slaves must be XOR'd externally. Figure 3 shows the necessary external logic for multi-chip systems. Write and read-modify-write cycles are carried out analogously. See the System Operation section for multi-chip wiring diagrams.

There are several pins used to define whether the 8206 will operate as a master or a slave. Tables 2 and 3 illustrate how these pins are tied.

The timing specifications for multi-chip systems must be calculated to take account of the external XOR gating in 3, 4, and 5-chip systems. Let tXOR be the delay for a single external TTL XOR gate. Then the following equations show how to calculate the relevant timing parameters for 2-chip (n=0), 3-chip (n=1), 4-chip (n=2), and 5-chip (n=2) systems:

Data-in to corrected data-out (read cycle) = TDVSV + TPVSV + TSVQV + ntXOR

Data-in to error flag (read cycle) = TDVSV + TPVEV + ntXOR

Data-in to correctable error flag (read cycle) = TDVSV + TPVSV + TSVCV + ntXOR

Write data to check-bits valid (full write cycle) = TQVQV + TPVSV + ntXOR

Data-in to check-bits valid (read-mod-write cycle) = TDVSV + TPVSV + TSVQV + TQVQV + TPVSV + 2ntXOR

Data-in to check-bits valid (non-correcting readmodify-write cycle) =

TDVQU + TQVQV + TPVSV + ntXOR

### **HAMMING CODE**

The 8206 uses a modified Hamming code which was optimized for multi-chip EDCU systems. The code is such that partial parity is computed by all 8206's in

parallel. No 8206 requires more time for propagation through logic levels than any other one, and hence no one device becomes a bottleneck in the parity operation. However, one or two levels of external TTL XOR gates is required in systems with three to five chips. The code appears in Table 4. The check bits are derived from the table by XORing or XNORing together the bits indicated by 'X's in each row corresponding to a check bit. For example, check bit 0 in the MASTER for data word 1000110110110111 will be "0." It should be noted that the 8206 will detect the gross-error condition of all lows or all highs.

Error correction is accomplished by identifying the bad bit and inverting it. Table 4 can also be used as an error syndrome table by replacing the 'X's with '1's. Each column then represents a different syndrome word, and by locating the column corresponding to a particular syndrome the bit to be corrected may be identified. If the syndrome cannot be located then the error cannot be corrected. For example, if the syndrome word is 00110111, the bit to be corrected is bit 5 in the slave one data word (bit 21).

The syndrome decoding is also summarized in Table 5, which can be used for error logging. By finding the appropriate syndrome word (starting with bit zero, the least significant bit), the result is either: 1) no error; 2) an identified (correctable) single bit error; 3) a double bit error; or 4) a multi-bit uncorrectable error.

Figure 3. External Logic For Multi-Chip Systems

### Table 4. Modified Hamming Code Check Bit Generation

Check bits are generated by XOR'ing (except for the CB0 and CB1 data bits, which are XNOR'ed in the Master) the data bits in the rows corresponding to the check bits. Note there are 6 check bits in a 16-bit system, 7 in a 32-bit system, and 8 in 48-or-more-bit systems.

### SYSTEM ENVIRONMENT

The 8206 interface to a typical 32 bit memory system is illustrated in Figure 4. For larger systems, the partial parity bits from slaves two to four must be

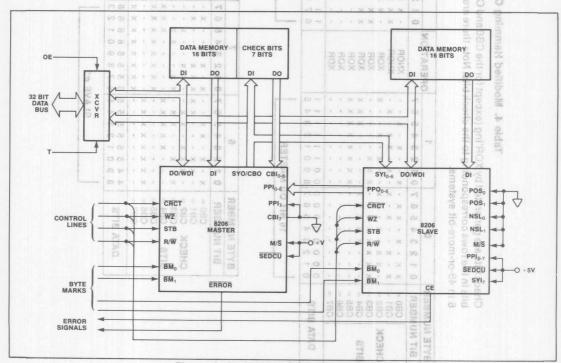

Figure 4. 32-Bit 8206 System Interface

XOR'ed externally, which calls for one level of XOR gating for three 8206's and two levels for four or five 8206's.

to the check bits memory held inactive, and then performing ordinary reads. The

The 8206 is designed for direct connection to the Intel 8207 Advanced Dynamic RAM Controller, due to be sampled in the first quarter of 1982. The 8207 has the ability to perform dual port memory control,

and Figure 5 illustrates a highly integrated dual port RAM implementation using the 8206 and 8207. The 8206/8207 combination permits such features as automatic scrubbing (correcting errors in memory during refresh), extending RAS and CAS timings for Read-Modify-Writes in single memory cycles, and automatic memory initialization upon reset. Together these two chips provide a complete dual-port, error-corrected dynamic RAM subsystem.

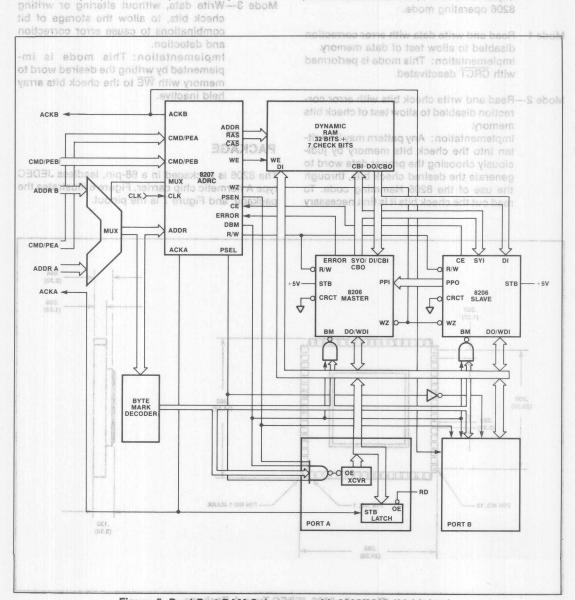

Figure 5. Dual Port RAM Subsystem with 8206/8207 (32-bit bus)

#### MEMORY BOARD TESTING aviil a stupi if bris

The 8206 lends itself to straightforward memory board testing with a minimum of hardware overhead. The following is a description of four common test modes and their implementation.

- Mode 0—Read and write with error correction.
  Implementation: This mode is the normal 8206 operating mode.
- Mode 1—Read and write data with error correction disabled to allow test of data memory.

  Implementation: This mode is performed with CRCT deactivated.

Mode 2-Read and write check bits with error cor-

rection disabled to allow test of check bits memory.

Implementation: Any pattern may be written into the check bits memory by judiciously choosing the proper data word to generate the desired check bits, through the use of the 8206 Hamming code. To

read out the check bits it is first necessary

to fill the data memory with all zeros, which may be done by activating WZ and incrementing memory addresses with WE to the check bits memory held inactive, and then performing ordinary reads. The check bits will then appear directly at the SYO outputs, with bits CB0 and CB1 inverted.

Mode 3—Write data, without altering or writing check bits, to allow the storage of bit combinations to cause error correction and detection.

Implementation: This mode is im-

Implementation: This mode is implemented by writing the desired word to memory with WE to the check bits array held inactive.

### PACKAGE

The 8206 is packaged in a 68-pin, leadless JEDEC type A hermetic chip carrier. Figure 6 illustrates the package, and Figure 7 is the pinout.

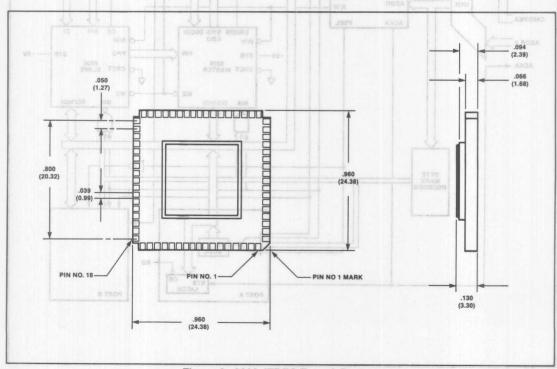

Figure 6. 8206 JEDEC Type A Package

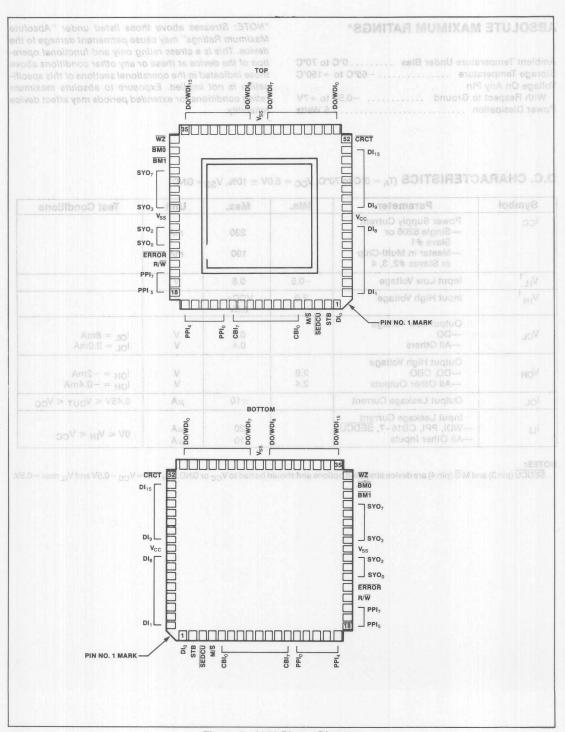

Figure 7. 8206 Pinout Diagram

### **ABSOLUTE MAXIMUM RATINGS\***

 \*NOTE: Stresses above those listed under "Absolute Maximum Ratings" may cause permanent damage to the device. This is a stress rating only and functional operation of the device at these or any other conditions above those indicated in the operational sections of this specification is not implied. Exposure to absolute maximum rating conditions for extended periods may affect device reliability.

## 8271/8271-6 PROGRAMMABLE FLOPPY DISK CONTROLLER

- IBM 3740 Soft Sectored Format Compatible
- Programmable Record Lengths
- m Multi-Sector Capability
- Maintain Dual Drives with Minimum Software Overhead Expandable to 4 Drives
- Automatic Read/Write Head Positioning and Verification

- Internal CRC Generation and Checking
- Programmable Step Rate, Settle-Time, Head Load Time, Head Unload Index Count
- Fully MCS-80<sup>TM</sup> and MCS-85<sup>TM</sup> Compatible
- Single +5V Supply
- 40-Pin Package

The Intel® 8271 Programmable Floppy Disk Controller (FDC) is an LSI component designed to interface one to 4 floppy disk drives to an 8-bit microcomputer system. Its powerful control functions minimize both hardware and software overhead normally associated with floppy disk controllers.

#### **FUNCTIONAL DESCRIPTION**

#### General

The 8271 Floppy Disk Controller (FDC) interfaces either two single or one dual floppy drive to an eight bit microprocessor and is fully compatible with Intel's new high performance MCS-85 microcomputer system. With minimum external circuitry, this innovative controller supports most standard, commonly-available flexible disk drives including the mini-floppy.

The 8271 FDC supports a comprehensive soft sectored format which is IBM 3740 compatible and includes provision for the designating and handling of bad tracks. It is a high level controller that relieves the CPU (and user) of many of the control tasks associated with implementing a floppy disk interface. The FDC supports a variety of high level instructions which allow the user to store and retrieve data on a floppy disk without dealing with the low level details of disk operation.

In addition to the standard read/write commands, a scan command is supported. The scan command allows the user program to specify a data pattern and instructs the FDC to search for that pattern on a track. Any application that is required to search the disk for information (such as point of sale price lookup, disk directory search, etc.), may use the scan command to reduce the CPU overhead. Once the scan operation is initiated, no CPU intervention is required.

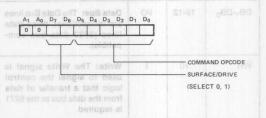

### **CPU Interface Description**

This interface minimizes CPU involvement by supporting a set of high level commands and both DMA and non-DMA type data transfers and by providing hierarchical status information regarding the result of command execution.

The CPU utilizes the control interface (see the Block diagram) to specify the FDC commands and to determine the result of an executed command. This interface is supported by five Registers which are addressed by the CPU via the A<sub>1</sub>, A<sub>0</sub>,  $\overline{\text{RD}}$  and  $\overline{\text{WR}}$  signals. If an 8080 based system is used, the  $\overline{\text{RD}}$  and  $\overline{\text{WR}}$  signals can be driven by the 8228's  $\overline{\text{I/OR}}$  and  $\overline{\text{I/OW}}$  signals. The registers are defined as follows:

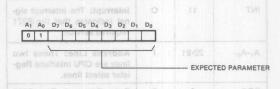

#### **Command Register**

The CPU loads an appropriate command into the Command Register which has the following format:

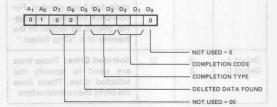

#### Parameter Register

Accepts parameters of commands that require further description; up to five parameters may be required, example:

### Result Register

The Result Register is used to supply the outcome of FDC command execution (such as a good/bad completion) to the CPU. The standard Result byte format is:

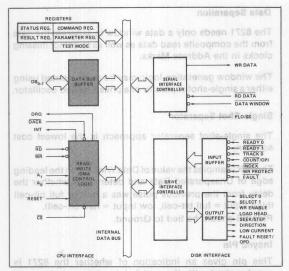

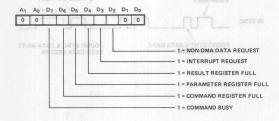

Figure 3. 8271 Block Diagram Showing CPU Interface Functions

#### Status Register

Reflects the state of the FDC.

#### **Reset Register**

Allows the 8271 to be reset by the program. Reset must be active for 11 or more chip clocks.

#### INT (Interrupt Line)

Another element of the control interface is the Interrupt line (INT). This line is used to signal the CPU that an FDC operation has been completed. It remains active until the result register is read.

#### **DMA Operation**

The 8271 can transfer data in either DMA or non DMA mode. The data transfer rate of a floppy disk drive is high enough (one byte every 32 µsec) to justify DMA transfer. In DMA mode the elements of the DMA interface are:

#### **DRQ:** DMA Request:

The DMA request signal is used to request a transfer of data between the 8271 and memory.

## DACK: DMA Acknowledge: 18001 Hosti Inemus ent bas

The DMA acknowledge signal notifies the 8271 that a DMA cycle has been granted.

### RD, WR: Read, Write sh sosheint svind side DDG edT

The read and write signals are used to specify the direction of the data transfer.

DMA transfers require the use of a DMA controller such as the Intel®8257. The function of the DMA controller is to provide sequential addresses and timing for the transfer at a starting address determined by the CPU. Counting of data block lengths is performed by the FDC.

To request a DMA transfer, the FDC raises DRQ. DACK and RD enable DMA data onto the bus (independently of CHIP SELECT). DACK and WR transfer DMA data to the FDC. If a data transfer request (read or write) is not serviced within 31  $\mu$ sec, the command is cancelled, a late DMA status is set, and an interrupt is generated. In DMA mode, an interrupt is generated at the completion of the data block transfer.

When configured to transfer data in non-DMA mode, the CPU must pass data to the FDC in response to the non-DMA data requests indicated by the status word. The data is passed to and from the chip by asserting the DACK and the RD or WR signals. Chip select should be inactive (HIGH).

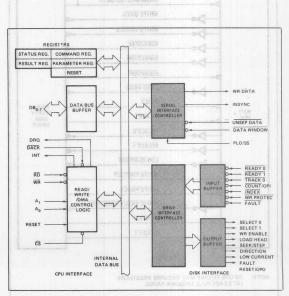

Figure 4. 8271 Block Diagram Showing Disk Interface

DRO: DMA Request:

#### **Disk Drive Interface**

The 8271 disk drive interface supports the high level command structure described in the Command Description section. The 8271 maintains the location of bad tracks and the current track location for two drives. However, with minor software support, this interface can support four drives by expanding the two drive select lines (select 0, select 1) with the addition of minimal support hardware.

The FDC Disk Drive Interface has the following major functions, and beau are signals attracted to seen and

#### **READ FUNCTIONS**

To request a DMA transfer, the

Generate the programmed step rate, head load time, head settling time, head unload delay, and monitor drive functions. When configured to transfer data in non-DM

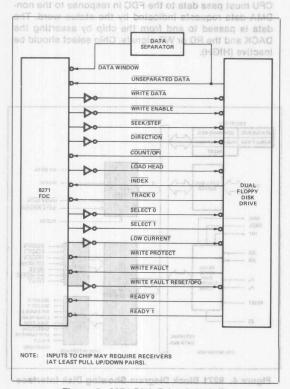

Figure 5. 8271 Disk Drive Interface

#### **Data Separation**

The 8271 needs only a data window to separate the data from the composite read data as well as to detect missing clocks in the Address Marks.

The window generation logic may be implemented using either a single-shot separator or a phase-locked oscillator.

#### Single-Shot Separator

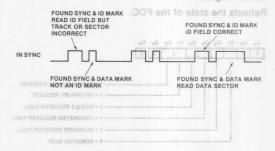

The single-shot separator approach is the lowest cost solution.

The FDC samples the value of Data Window on the leading edge of Unseparated Data and determines whether the delay from the previous pulse was a half or full bit-cell (high input = full bit-cell, low input = half bit-cell).

PLO/SS should be tied to Ground.

#### Insync Pin

This pin gives an indication of whether the 8271 is synchronized with the serial data stream during read operations. This pin can be used with a phase-locked oscillator for soft and hard locking.

Allows the 8271 to be reset by the program. Reset must be active for 11 or more chip clocks.

Another element of the control interface is the interrupt line (INT). This line is used to signal the CPU that an FDC operation has been completed. It remains active until the

The 8271 can transfer data in either DMA or non DMA In DMA mode the elements of the DMA interface are:

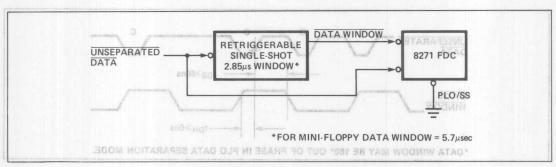

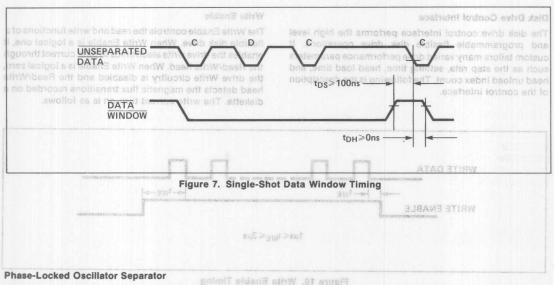

Figure 6. Single-Shot Data Separator Block Diagram

#### **Phase-Locked Oscillator Separator**

The FDC samples the value of Data Window on the leading edge of Unseparated Data and determines whether the pulse represents a Clock or Data Pulse.

Insync may be used to provide soft and hard locking control for the phase-locked oscillator.

PLO/SS should be tied to Vcc (+5V).

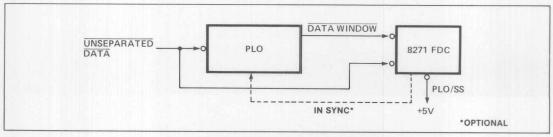

Figure 8. PLO Data Separator Block Diagram

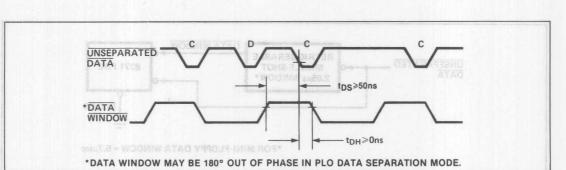

Figure 9. PLO Data Window Timing

#### Disk Drive Control Interface

The disk drive control interface performs the high level and programmable flexible disk drive operations. It custom tailors many varied drive performance parameters such as the step rate, settling time, head load time, and head unload index count. The following is the description of the control interface.

#### Write Enable

The Write Enable controls the read and write functions of a flexible disk drive. When Write Enable is a logical one, it enables the drive write electronics to pass current through the Read/Write head. When Write Enable is a logical zero, the drive Write circuitry is disabled and the Read/Write head detects the magnetic flux transitions recorded on a diskette. The write current turn-on is as follows.

edge of Unseparated Data and determines whether the

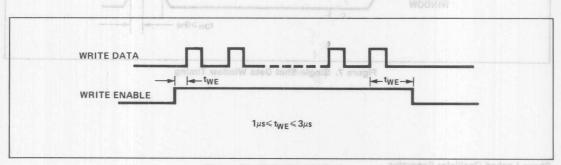

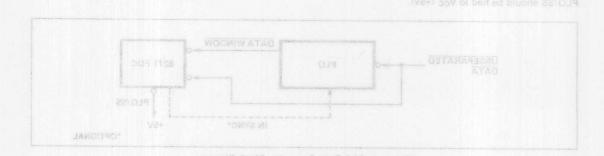

Figure 10. Write Enable Timing pnibool bash bas the ebivorg of besu ed yam anyani gnibsel an nor

1-123

l<sub>9</sub>ini

#### Seek Control

Seek Control is accomplished by Seek/Step, Direction, and Count pins and can be implemented two ways to provide maximum flexibility in the subsystem design. One instance is when the programmed step rate is not equal to zero. In this case, the 8271 uses the Seek/Step and Direction pins (the Seek/Step pin becomes a Step pin). Programmable Step timing parameters are shown.

Another instance is when the programmable step rate is equal to zero, in which case the 8271 holds the seek line high until the appropriate number of user-supplied step pulses have been counted on the count input pin.

The Direction pin is a control level indicating the direction in which the R/W head is stepped. A logic high level on this line moves the head toward the spindle (step-in). A logic low level moves the head away from the spindle (step-out).

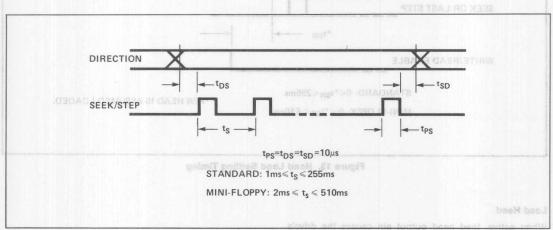

Figure 11. Seek Timing effectable and no behalf of oil band ethylogen

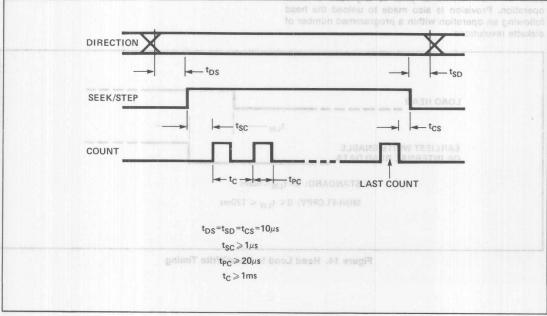

Figure 12. Seek/Step/Count Timing

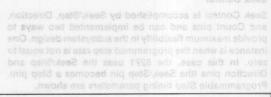

#### Head Seek Settling Time Toutness at his notices Q and

The 8271 allows the head settling time to be programmed from 0 to 255ms, in increments of 1ms.

The head settling time is defined as the interval of time from completion of the last step to the time when reading or writing on the diskette is possible (R/W Enable). The R/W head is assumed loaded.

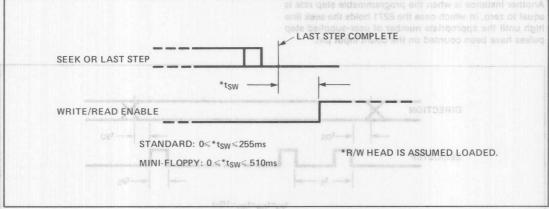

Figure 13. Head Load Settling Timing

#### Load Head

When active, load head output pin causes the drive's read/write head to be loaded on the diskette. When the head is initially loaded, there is a programmed delay (0 to 60ms in 4ms increments) prior to any read or write operation. Provision is also made to unload the head following an operation within a programmed number of diskette revolutions.

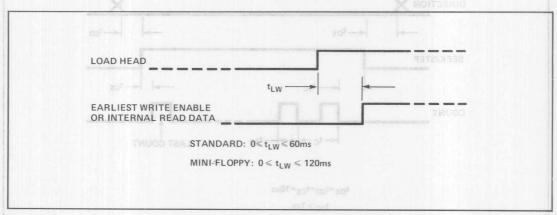

Figure 14. Head Load to Read/Write Timing

The Index input is used to determine "Sector not found" status and to initiate format track/read ID commands and head unload Index and Count operations.

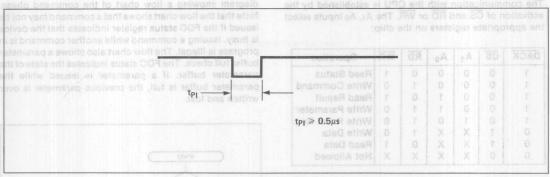

Figure 15. Index Timing and to beaugmos at nottatego DOR and

#### Track 0

This input pin indicates that the diskette is at track 0. During any seek operation, the stepping out of the actuator ceases when the track 0 pin becomes active.

#### Select 1, 0

Only one drive may be selected at a time. The Input/Output pins that must be externally qualified with Select 0 and Select 1 are:

Unseparated Data
Data Window
Write Enable
Seek/Step
Count/Optional Input
Load Head
Track 0
Low Current
Write Protect
Write Fault
Fault Reset/Optional Output
Index

When a new set of select bits is specified by a new command or the FDC finishes the index count before head unload, the following pins will be set to the 0 state:

Write Enable (35)
Seek/Step (36)
Direction (37)
Load Head (38)
Low Head Current (39)

The select pins will be set to the state specified by the command or both are set to zero following the index count before head unload.

### Low Current emoting at saving bnammoo ent pninub

This output pin is active whenever the physical track location of the selected drive is greater than 43. Generally

this signal is used to enable compensation for the lower velocities encountered while recording on the inner tracks.

### Write Protect MRAD OF MWG STI MO STITUS SHIT SAAHR MOFTUDSKS

The 8271 will not write to a disk when this input pin is active and will interrupt the CPU if a Write attempt is made. Operations which check Write Protect are aborted if the Write Protect line is active.

This signal normally originates from a sensor which detects the presence or absence of the Write Protect hole in the diskette jacket.

#### Write Fault and Write Fault Reset

The Write Fault input is normally latched by the drive and indicates any condition which could endanger data integrity. The 8271 interrupts the CPU anytime Write Fault is detected during an operation and immediately resets the Write Enable, Seek/Step, Direction, and Low Current signals. The write fault condition can be cleared by using the write fault reset pin. If the drive being used does not support write fault, then this pin should be connected to  $\rm V_{CC}$  through a pull-up resistor.

#### Ready 1, 0

These two pins indicate the functional status of the disk drives. Whenever an operation is attempted on a drive which is not ready, an interrupt is generated. The interface continually monitors this input during an operation and if a Not Ready condition occurs, immediately terminates the operation. Note that the 8271 latches the Not Ready condition and it can only be reset by the execution of a Read Drive Status command. For drives that do not support a ready signal, either one can be derived with a one shot and the index pulse, or the ready inputs can be grounded and Ready determined through some software means.

# The Command Phase

As an 8080 peripheral device, the 8271 accepts commands from the CPU, executes them and provides a RESULT back to the 8080 CPU at the end of command execution. The communication with the CPU is established by the activation of  $\overline{CS}$  and  $\overline{RD}$  or  $\overline{WR}$ . The A<sub>1</sub>, A<sub>0</sub> inputs select the appropriate registers on the chip:

PRINCIPLES OF OPERATION

DACK	CS	A <sub>1</sub>	Ao	RD	WR	Operation
1	0	0	0	0	1	Read Status
1	0	0	0	1	0	Write Command
1	0	0	1	0	1	Read Result
1	0	0	1	1	0	Write Parameter
1	0	1	0	1	0	Write Reset Reg
0	1	X	X	1	0	Write Data
0	1	X	X	0	1	Read Data
0	0	X	X	X	X	Not Allowed

The FDC operation is composed of the following sequence of events.

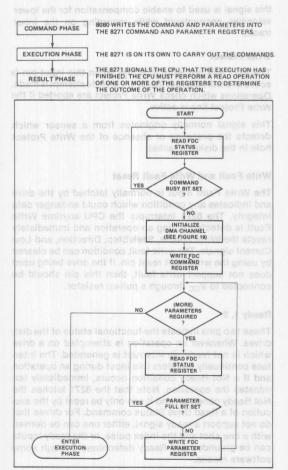

Figure 16. Passing the Command and Parameters to the 8271

The software writes a command to the command register. As a function of the command issued, from zero to five parameters are written to the parameter register. Refer to diagram showing a flow chart of the command phase. Note that the flow chart shows that a command may not be issued if the FDC status register indicates that the device is busy. Issuing a command while another command is in progress is illegal. The flow chart also shows a parameter buffer full check. The FDC status indicates the state of the parameter buffer. If a parameter is issued while the parameter buffer is full, the previous parameter is over written and lost.

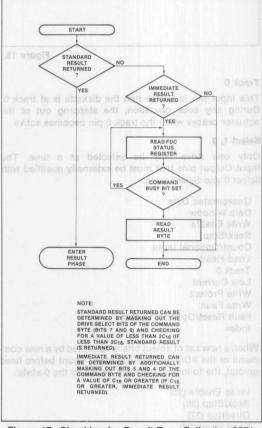

Figure 17. Checking for Result Type Following 8271 Command and Parameters

## The Execution Phase

During the execution phase the operation specified during the command phase is performed. During this phase, there is no CPU involvement if the system utilizes DMA for the data transfers. The execution phase of each command is discussed within the detailed command descriptions. The following table summarizes many of the basic execution phase characteristics.

1-127 AFN-00223B

#### EXECUTION PHASE BASIC CHARACTERISTICS

The following table summarizes the various commands with corresponding execution phase characteristics.

Explanation of the execution phase characteristics table.

#### 1. Deleted Data Processing

If deleted data is encountered during an operation that is marked skip in the table, the deleted data record is not transferred into memory, but the record is counted. For example, if the command and parameters specify a read of five records and one of the records was written with a deleted data mark, four records are transferred to memory. The deleted data flag is set in the result byte. However, if the operation is marked transfer, all data is transferred to memory regardless of the type of data mark.

#### 2. Head

The Head column in the table specifies whether the Read/Write head will be loaded or not. If the table specifies load, the head is loaded after it is positioned over the track. The head loaded by a command remains loaded until the user specified number of index pulses have occurred.

Bits 4 and 3: Completion Type

#### 3. Ready

The Ready column indicates if the ready line (Ready 1, Ready 0) associated with the selected drive is checked. A not ready state is latched by the 8271 until the user executes a read status command.

#### 4. Write Protect

The operations that are marked check Write Protect are immediately aborted if Write Protect line is active at the beginning of an operation.

#### 5. Seek

Many of the 8271 commands cause a seek to the desired track. A current track register is maintained for each drive or surface.

#### 6. Seek Check

Operations that perform Seek Check verify that selected data in the ID field is correct before the 8271 accesses the data field.

register. Whenever the FDC is busy processing a

Bit 6: Command Full

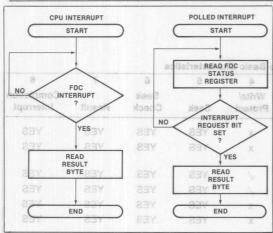

Figure 18. Getting the Result

#### The Result Phase

During the Result Phase, the FDC notifies the CPU of the outcome of the command execution. This phase may be initiated by: a stow

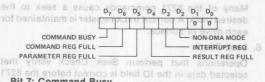

- 1. The successful completion of an operation.
- 2. An error detected during an operation.

#### PROGRAMMING

A <sub>1</sub>	A <sub>0</sub>	CS RD	CS WR
0	0	Status Reg	Command Reg
0	1	Result Reg	Parameter Reg
1	0	_	Reset Reg
1	1	_	Write Protect

#### STATUS REGISTER

#### **FDC Status**

#### Bit 7: Command Busy

The command busy bit is set on writing to the command register. Whenever the FDC is busy processing a command, the command busy bit is set to a one. This bit is set to zero after the command is completed.

accesses the data field.

#### Bit 6: Command Full

The command full bit is set on writing to the command buffer and cleared when the FDC begins processing the command.

#### Bit 5: Parameter Full

This bit indicates the state of the parameter buffer. This bit is set when a parameter is written to the FDC and reset after the FDC has accepted the parameter.

#### Bit 4: Result Full TOARAND DISAS BRAMS MOTTUDENS

This bit indicates the state of the result buffer. It is valid only after Command Busy bit is low. This bit is set when the FDC finishes a command and is reset after the result byte is read by the CPU. The data in the result buffer is valid only after the FDC has completed a command. Reading the result buffer while a command is in progress yields no useful information.

#### **Bit 3: Interrupt Request**

This bit reflects the state of the FDC INT pin. It is set when FDC requests attention as a result of the completion of an operation or failure to complete an intended operation. This bit is cleared by reading the result register. GAOJ

#### Bit 2: Non-DMA Data Request

When the FDC is utilized without a DMA controller, this bit is used to indicate FDC data requests. Note that in the non-DMA mode, an interrupt is generated (interrupt request bit is set) with each data byte written to or read from the diskette.

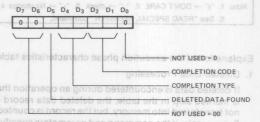

#### Bits 1 and 0:

Not used (zero returned).

After reading the Status Register, the CPU then reads the Result Register for more information.

#### THE RESULT REGISTER

This byte format facilitates the use of an address table to look up error routines and messages. The standard result byte format is:

## read of five records and one of the recor: 8 that T

#### Not used (zero returned). I sham also betsleb a ritiw

## to memory. The deleted data flag is set in the

Deleted Data Found: This bit is set when deleted data is encountered during a transaction.

### Bits 4 and 3: Completion Type

The completion type field provides general information regarding the outcome of an operation.

The completion type field provides general information regarding the outcome of an operation.

11	01	ADPLIANTED	WU	71 THE
		sevom bnammos		
11 3080	r verifting the	ading the head o		ioritiv

It is important to note the hierarchical structure of the result byte. In very simple systems where only a GO-NO GO result is required, the user may simply branch on a zero result (a zero result is a good completion). The next level of complexity is at the completion type interface. The completion type supplies enough information so that the software may distinguish between fatal and non-fatal errors. If a completion type 01 occurs, ten retries should be performed before the error is considered unrecoverable.

The Completion Type/Completion Code interface supplies the greatest detail about each type of completion. This interface is used when detailed information about the transaction completion is required.

Function: The Reset command emulates the action of the reset pin. It is issued by outputting a one followed by a zero to the Reset register.

- 1. The drive control signals are forced low.
- 2. An in-progress command is aborted.
- 3. The FDC status register flags are cleared.
- 4. The FDC enters an idle state until the next command is

Reset must be active for 10 or more clock cycles.

#### SPECIFY COMMAND

Many of the interface characteristics of the FDC are specified by the systems software. Prior to initiating any drive operation command, the software must execute the three specify commands. There are two types of specify commands selectable by the first parameter issued.

#### First Parameter Specify Type

0DH	Initialization
10H	Load bad Tracks Surface '0'
18 <sub>H</sub>	Load bad Tracks Surface '1'

The Specify command is used prior to performing any diskette operation (including formatting of a diskette) to define the drive's inherent operating characteristics and also is used following a formatting operation or installation of another diskette to define the locations of bad tracks. Since the Specify command only loads internal registers within the 8271 and does not involve an actual diskette operation, command processing is limited to only Command Phase. Note that once the operating characteristics and bad tracks have been specified for a given drive and diskette, redefining these values need only be done if a diskette with unique bad tracks is to be used or if the system is powered down.

#### initialization:

1	sup:	Not	Met	net e		01			90	

Parameter 0: 10<sub>H</sub> = Load Surface zero bad tracks 18<sub>H</sub> = Load Surface one bad track

Parameter 1:000 000 00

Bad track address number 1 (Physical Address).

It is recommended to program both bad tracks and current track to FF<sub>H</sub> during initialization.

### SEEK COMMAND

The seek command moves the head to the specified track without loading the head or verifying the track.

The seek operation uses the specified bad tracks to compute the physical track address. This feature insures that the seek operation positions the head over the correct track

When a seek to track zero is specified, the FDC steps the head until the track 00 signal is detected.

If the track 00 signal is not detected within (FF)<sub>H</sub> steps, a track 0 not found error status is returned.

A seek to track zero is used to position the read/write head when the current head position is unknown (such as after a power up).

	A	A <sub>0</sub>	D <sub>7</sub>	D <sub>6</sub>	D <sub>5</sub>	D <sub>4</sub>	D <sub>3</sub>	D <sub>2</sub>	D <sub>1</sub>	D <sub>0</sub>
CMD:	0	0	SEL 1	SEL 0	1	0	980	0	0	1
PAR:	0	1	TRAC	K ADD	RESS 0	255				

Seek operations are not verified. A subsequent read or write operation must be performed to determine if the correct track is located.

#### **READ DRIVE STATUS COMMAND**

This command is used to interrogate the drive status. Upon completion the result register will hold the final drive status.

0	301	0	SEL 1	SEL 0	1	0	1	1.	0	
			-				-		_	-
men.										
RESI	111	T. F4	CH BIT	INDIC	ATESCI	IRREN	TSTAT	E OF I	UPLIT PI	NIS
RESI A1		T: EA	ACH BIT	INDIC D <sub>6</sub>	ATES CI	URREN'	T STAT	E OF II	NPUT PII	NS.
									D <sub>1</sub>	0

\*Note the two ready bits are zero latching. Therefore, to clear the drive not ready condition, assuming the drive is ready, and to detect it via software, one must issue this command twice.

Double/Single Actuator: Selects single or double actuator mode. If the single actuator mode is selected, the FDC assumes that the physical track location of both disks is always the same. This mode facilitates control of a drive which has a single actuator mechanism to move two heads.

surfaces) of the disligite. On double-sided disligites, the

### corresponding top and bottom tracks are referred to fill\*

Data Transfer Mode: This bit selects the data transfer mode. If this bit is a zero, the FDC operates in the DMA mode (DMA Request/ACK). If this bit is a one, the FDC operates in non-DMA mode. When the FDC is operating in DMA mode, interrupts are generated at the completion of commands. If the non-DMA mode is selected, the FDC generates an interrupt for every data byte transferred.

diskettel, an index pulse is generated to indicate the

1-132 AFN-00223B

<sup>\*</sup>Bits 0 and 1 are initialized to zero. On a find a set initialized to zero.

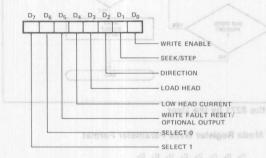

#### Non-DMA Transfers in DMA Mode

If the user desires, he may retain the use of interrupts generated upon command completions. This mode is accomplished by selecting the DMA capability, but using the DMA REQ/ACK pins as effective INT and CS signals, respectively.

#### **Drive Control Input Port**

Reading this port will give the CPU exactly the data that the FDC sees at the corresponding pins. Reading this port will update the drive not ready status, but will not clear the status. (See Read Drive Status Command for Bit locations.)

#### **Drive Control Output Port Format**

Each of these signals correspond to the chip pin of the same name. On standard-sized drives with write fault detection logic, bit 5 is set to generate the write fault reset signal. This signal is used to clear a write fault indication within the drive. On mini-sized drives, this bit can be used to turn on or off the drive motor prior to initiating a drive operation. A time delay after turn on may be necessary for the drive to come up to speed. The register must be read prior to writing the register in order to save the states of the remaining bits. When the register is subsequently written to modify bit 5, the remaining bits must be restored to their previous states.

# IBM DISKETTE GENERAL FORMAT

The IBM Flexible Diskette used for data storage and retrieval is organized into concentric circular paths or TRACKS. There are 77 tracks on either one or both sides (surfaces) of the diskette. On double-sided diskettes, the corresponding top and bottom tracks are referred to as a CYLINDER. Each track is further divided into fixed length sections or SECTORS. The number of sectors per track—26, 15 or 8—is determined when a track is formatted and is dependent on the sector length—128, 256 or 512 bytes respectively—specified.

All tracks on the diskette are referenced to a physical index mark (a small hole in the diskette). Each time the hole passes a photodetector cell (one revolution of the diskette), an Index pulse is generated to indicate the logical beginning of a track. This index pulse is used to initiate a track formatting operation.

#### **Track Format**

Each Diskette Surface is divided into 77 tracks with each track divided into fixed length sectors. A sector can hold a whole record or a part of a record. If the record is shorter than the sector length, the unused bytes are filled with binary zeros. If a record is longer than the sector length, the record is written over as many sectors as its length requires. The sector size that provides the most efficient use of diskette space can be chosen depending upon the record length required.

Tracks are numbered from 00 (outer-most) to 76 (inner-most) and are used as follows:

TRACK 00 reserved as System Label Track TRACKS 01 through 74 used for data TRACKS 75 and 76 used as alternates.

Each sector consists of an ID field (which holds a unique address for the sector) and a data field.

The ID field is seven bytes long and is written for each sector when the track is formatted. Each ID field consists of an ID field Address Mark, a Cylinder Number byte which identifies the track number, a Head Number byte which specifies the head used (top or bottom) to access the sector, a Record Number byte identifying the sector number (1 through 26 for 128 byte sectors), an N-byte specifying the byte length of the sector and two CRC (Cyclic Redundancy Check) bytes.

The Gaps separating the index mark and the ID and data fields are written on a track when it is formatted. These gaps provide both an interval for switching the drive electronics from reading or writing and compensation for rotational speed and other diskette-to-diskette and drive-to-drive manufacturing tolerances to ensure that data written on a diskette by one system can be read by another (diskette interchangeability).

#### **IBM Format Implementation Summary**

#### **Track Format**

The disk has 77 tracks, numbered physically from 00 to 76, with track 00 being the outermost track. There are logically 75 data tracks and two alternate tracks. Any two tracks may be initialized as bad tracks. The data tracks are numbered logically in sequence from 00 to 74, skipping over bad tracks (alternate tracks replace bad tracks). Note: In IBM format track 00 cannot be a bad track.

#### **Sector Format**

Each track is divided into 26, 15, or 8 sectors of 128, 256, or 512 bytes length respectively. The first sector is numbered 01, and is physically the first sector after the physical index mark. The logical sequence of the remaining sectors may be nonsequential physically. The location of these is determined at initialization by CPU software.

Each sector consists of an ID field and a data field. All fields are separated by gaps. The beginning of each field is indicated by 6 bytes of (00)<sub>H</sub> followed by a one byte address mark.

#### **Address Marks**

Address Marks are unique bit patterns one byte in length which are used to identify the beginning of ID and Data fields. Address Mark bytes are unique from all other data

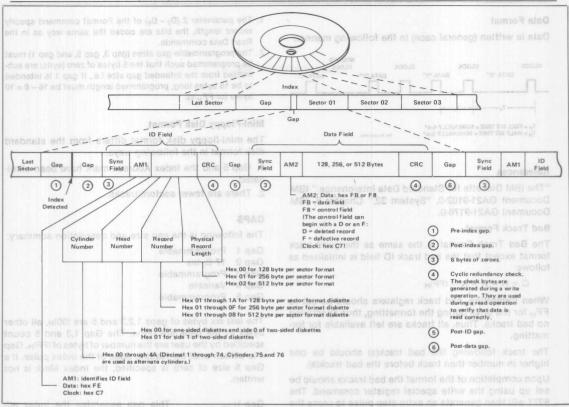

Figure 20. Track Format

bytes in that certain bit cells do not contain a clock bit (all other data bytes have clock bits in every bit cell.) There are four different types of Address Marks used. Each of these is used to identify different types of fields.

### Index Address Mark nem stab entr

The Index Address Mark is located at the beginning of each track and is a fixed number of bytes in front of the first record.

#### **ID Address Mark**

The ID Address Mark byte is located at the beginning of each ID field on the diskette.

### Data Address Mark

The Data Address Mark byte is located at the beginning of each non-deleted Data Field on the diskette.

#### **Deleted Data Address Mark**

The Deleted Data Address Mark byte is located at the beginning of each deleted Data Field on the diskette.

Address Mark Summary	Clock Pattern	Data Pattern

H = Head Address

R = Record (Sector) Address, 01-26

N = Record (Sector) Length, 00-02

Note: Sector Length =  $128 \times 2^{N}$  bytes

CRC = 16 Bit CRC Character (See Below)

### Data Field

MARK	DATA	CRC	ODO
INICALLY	DAIA	UNL	CRC

Data is 128, 256, or 512 bytes long.

Note: All marks, data, ID characters and CRC characters are recorded and read most significant bit first.

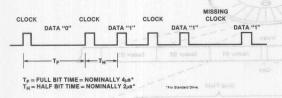

## CRC Characters bos 1758 and most elamiple sham

The 16-bit CRC character is generated using the generator polynominal X16 + X12 + X5 + 1, normally initialized to (FF) $_{\rm H}$ . It is generated from all characters (except the CRC in the ID or data field), including the data (not the clocks) in the address mark. It is recorded and read most significant bit first.

#### **Data Format**

Data is written (general case) in the following manner:

"The IBM Diskette for Standard Data Interchange," IBM Document GA21-9182-0. "System 32," Chapter 8, IBM Document GA21-9176-0.

### Bad Track Format

The Bad Track Format is the same as the good track format except that the bad track ID field is initialized as follows:

$$C = H = R = N = (FF)_H$$

When formatting, bad track registers should be set to FFH for the drive during the formatting, thus specifying no bad tracks. Thus, all tracks are left available for formatting.

The track following the bad track(s) should be one higher in number than track before the bad track(s).

Upon completion of the format the bad tracks should be set up using the write special register command. The 8271 will then generate an extra step pulse to cross the bad track, locating a new track that now happens to be an extra track out.

#### **Format Track**

	1164	711

PAR:	0	1	RECO	RECORD LENGTH NO. OF SECTORS/TRACK							
PAR:	0	1	GAP	GAP 5 SIZE MINUS 6							
PAR:	0	1	GAP	1 SIZE	MINUS	6	JANJ	3165 0	21	377	

The format command can be used to initialize a disk track compatible with the IBM 3740 format. A Shugart "IBM Type" mini-floppy format may also be generated.

The Format command can be used to initialize a diskette, one track at a time. When format command is used, the program must supply ID fields for each sector on the track. During command execution, the supplied ID fields (track head sector addresses and the sector length) are written sequentially on the diskette. The ID address marks originate from the 8271 and are written automatically as the first byte of each ID field. The CRC character is written in the last two bytes of the ID field and is derived from the data written in the first five bytes. During the formatting operation, the data field of each sector is filled with data pattern (E5)H. The CRC, derived from the data pattern is also appended to the last byte.

- 1. The parameter 2 (D7 D5) of the Format command specify record length, the bits are coded the same way as in the Read Data commands.
- 2. The programmable gap sizes (gap 3, gap 5, and gap 1) must be programmed such that the 6 bytes of zero (sync) are subtracted from the intended gap size i.e., if gap 1 is intended to be 16 bytes long, programmed length must be 16-6=10bytes (of FFH's).

### Mini-Floppy Disk Format

The mini-floppy disk format differs from the standard disk format in the following ways:

- 1. Gap 5 and the Index Address mark have been eliminated.
- 2. There are fewer sectors/tracks.

#### **GAPS**

The following is the gap size and description summary:

Gap 1 Programmable Gap 2 17 Bytes Gap 3 Programmable Gap 4 Variable Gap 5 Programmable

The last six bytes of gaps 1,2,3 and 5 are (00)H, all other bytes in the gaps are (FF)H. The Gap 1,3 and 5 count specified by the user are the number of bytes of (FF)H. Gap 4 is written until the leading edge of the index pulse. If a Gap 5 size of zero is specified, the Index Mark is not written.

Gap 1: N bytes FF's

This gap separates the index address mark of the index pulse from 6 bytes 0's for sync the first ID mark. It is used to protect the first ID field from a write on the last physical sector of the current track.

Gap 2: 11 bytes FF's

This gap separates the ID field from the data mark and field such that 6 bytes 0's for sync during a write only the data field and to most all solved will be changed even if the write gate turns on early, due to drive speed changes.

Gap 3:

This gap separates a data area from N bytes FF's the next ID field. It is used so that 6 bytes 0's for sync during drive speed changes the next ID mark will not be overwritten, thus causing loss of data.

Gap 4: FF's only

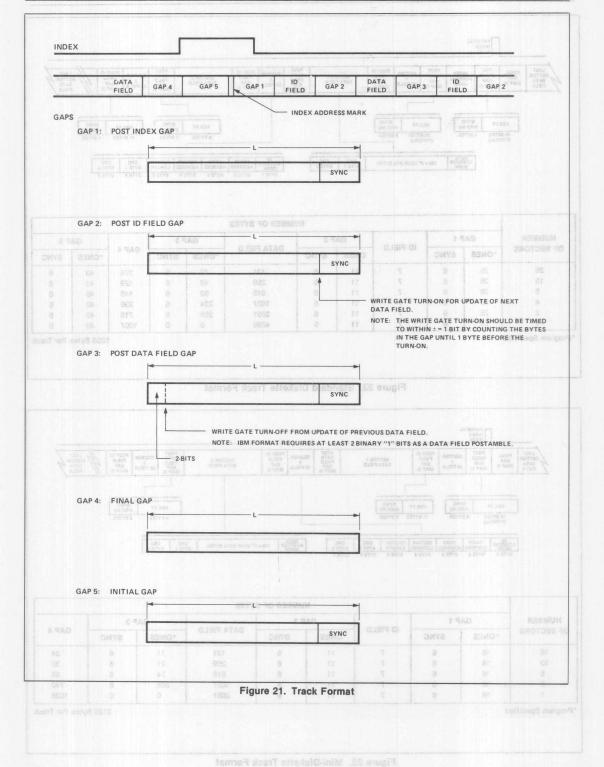

This gap fills out the rest of the disk and is used for slack during formatting. During drive speed variations and is betseen at all this gap will shrink or grow if the disk is re-formatted.

Gap 5: N bytes FF's

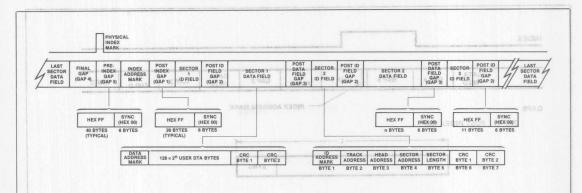

This gap separates the last sector from the Index Address mark and 6 bytes 0's for sync is used to assure that the index address mark is not destroyed by writing on the last physical data sector on the track.

The number of FF bytes is programmable for gaps 1, 3 and 5.

The Read ID command transfers the specified number of ID fields into memory (beginning with the first ID field after Index). The CRC character is checked but not transferred.

These fields are entered into memory in the order in which they are physically located on the disk, with the first field being the one starting at the index pulse.

#### **Data Processing Commands**

All the routine Read/Write commands examine specific drive status lines before beginning execution, perform an implicit seek to the track address and load the drive's read/write head. Regardless of the type of command (i.e., read, write or verify), the 8271 first reads the ID field(s) to verify that the correct track has been located (see sector not found completion code) and also to locate the addressed sector. When a transfer is complete (or cannot be completed), the 8271 sets the interrupt request bit in the status register and provides an indication of the outcome of the operation in the result register.

If a CRC error is detected during a multisector transfer, processing is terminated with the sector in error. The address of the failing sector number can be determined by examining the Scan Sector Number register using the Read Special Register command.

Full power of the multisector read/write commands can be realized by doing DMA transfer using Intel® 8257 DMA Controller, For example, in a 128 byte per sector multisector write command, the entire data block (containing 128 bytes times the number of sectors) can be located in a disk memory buffer. Upon completion of the command phase, the 8271 begins execution by accessing the desired track, verifying the ID field, and locating the data field of the first record to be written. The 8271 then DMA-accesses the first sector and starts counting and writing one byte at a time until all 128 bytes are written. It then locates the data field of the next sector and repeats the procedure until all the specified sectors have been written. Upon completion of the execution phase the 8271 enters into the result phase and interrupts the CPU for availability of status and completion results. Note that all read/write commands, single or multisector are executed without CPU intervention.

Note, execution of multi-sector operations are faster if the sectors are *not* interleaved. To be detailed by the sectors are not interleaved.

## Read Commands Dexe enged ITS8 art seeing braining

## Function 1000 state bas iotoes lent ent sessoon-AMO

The read command transfers data from a specified disk record or group of records to memory. The operation of this command is outlined in execution phase table.

## Write Commands or no felamos and curate to villosliava

Write Data, Write Deleted Data.

#### Function

The write command transfers data from memory to a specified disk record or group of records.

#### **Verify Command**

Verify Data and Deleted Data.

#### Function

The verify command is identical to the read data and deleted data command except that the data is not transferred to memory. This command is used to check that a record or a group of records has been written correctly by verifying the CRC character.

Command  $D_2 = 0$  Scan Data

D<sub>2</sub> = 1 Scan Data and Deleted Data

Scan Commands, Scan Data and Scan Data and Deleted Data, are used to search a specific data pattern or "key" from memory. The 8271 FDC operation during a scan is unique in that data is read from memory and from the diskette simultaneously.

During the scan operation, the key is compared repetitively (using the 8257 DMA Controller in auto load mode) with the data read from the diskette (e.g., an eight byte key would be compared with the first eight bytes (1-8) read from the diskette, the second eight bytes (9-16), the third eight bytes (17-24), etc.). The scan operation is concluded when the key is located or when the specified number of sectors have been searched without locating the key. When concluded, the 8271 FDC requests an interrupt. The program must then read the result register to determine if the scan was successful (if the key was located). If successful, several of the FDC's special registers can be examined (read special registers command) to determine more specific information relating to the scan (i.e., the sector number in which the key was located, and the number of bytes within the sector that were not compared when the key was located).

The 8271 does not do a sliding scan, it does a fixed block linear search. This means the key in memory is compared to an equal length block in a sector; when these blocks meet the scan conditions the scan will stop. Otherwise, the scan continues until all the sectors specified have been searched.

The following factors regarding key length must be considered when establishing a key in memory.

1. When searching multiple sectors, the length of the key must be evenly divisible into the sector length to prevent the key from being split at subsequent sector boundaries. Since the character FF<sub>H</sub> is not compared, the key in memory can be padded to the required length using this character. For example, if the actual pattern compared on the diskette is twelve characters in length, the field length should be sixteen and four bytes of FF<sub>H</sub>

loini

would be appended to the key. Consequently, the last block of sixteen bytes compared within the first sector would end at the sector boundary and the first byte of the next sector would be compared with the first byte of the key. Splitting data over sector boundarys will not work properly since the FDC expects the start of key at each sector boundary.

2. Since the first byte of the key is compared with the first byte of the sector, when the pattern does not begin with the first byte of the sector, the key must be offset using the character FF16. For example, if the first byte of a nine byte pattern begins on the fifth byte of the sector, four bytes of FF16 are prefixed to the key (and three bytes of FF16 are appended to the key to meet the length requirement) so that the first actual comparison begins on the fifth byte.

The Scan Commands require five parameters:

#### Parameter 0, Track Address

Specifies the track number containing the sectors to be scanned. Legal values range from  $00_{\rm H}$  to  $4C_{\rm H}$  (0 to 76) for a standard diskette and from  $00_{\rm H}$  to  $22_{\rm H}$  (0 to 34) for a mini-sized diskette.

#### Parameter 1, Sector Address

Specifies the first sector to be scanned. The number of sectors scanned is specified in parameter 2, and the order in which sectors are scanned is specified in parameter 3.

#### Parameter 2. Sector Length/Number of Sectors

The sector length field (bits 7-5) specifies the number of data bytes allocated to each sector (see parameter 2, routine read and write commands for field interpretation). The number of sectors field (bits 4-0) specifies the number of sectors to be scanned. The number specified ranges from one sector to the physical number of sectors on the track

#### Parameter 3

D<sub>7</sub>-D<sub>6</sub>: Indicate scan type

00-EQ Scan for each character within the field length (key) equal to the corresponding character within the disk sector. The scan stops after the first equal condition is met.

01-GEQ Scan for each character within the disk sector greater than or equal to the corresponding character within the field length (key). The scan stops after the first greater than or equal condition is met.

10-LEQ Scan for each character within the disk sector less than or equal to the corresponding character within the field length (key). The scan stops after the first less than or equal condition is met.

D<sub>5</sub>-D<sub>0</sub>: Step Size: The Step Size field specifies the offset to the next sector in a multisector scan. In this case, the next sector address is generated by adding the Step Size to the current sector address.

### Parameter 4, Field Length

8271/8271-6

Specifies the number of bytes to be compared (length of key). While the range of legal values is from 1 to 255, the field length specified should be evenly divisible into the sector length to prevent the key from being split at sector boundaries, if the multisector scan commands are used.

### **Scan Command Results**

More detailed information about the completion of Scan Commands may be obtained by executing Read Special Register commands.

## Read Special Register - ritorial biast mumikam jostA maos

Parameter Results

- Of The sector <u>number</u> of the sector in which the specified scan data pattern was located.
- MSB Count The number of 128 byte blocks remaining to be compared in the current sector when the scan data pattern was located. This register is decremented with each 128 byte block read.
- be compared in the current sector when the scan data pattern is located. This register is initialized to 128 and is decremented with each byte compared.

Upon a scan met condition, the equation below can be used to determine the last byte in the located pattern.

Pointer = sector length - ((Register 14H)\*128 + (Register 13H))

first byte of the key. Splitting data over sector bound-

arys will not work properly since the FDC expects the

#### NOTES

- Field Length Each record is partitioned into a number of fields equal to the record size divided by the field length.

  Note that the record size should be evenly divisable by the field length to insure proper operation of multi record scan. Also, maximum field length = 256 bytes.
- 2. Key The key is a string of bytes located in the user system memory. The key length should equal the field length.

  By programming the 8257 DMA Controller into the auto load mode, the key will be recursively read in by the chip (once per field).
- Completion Code Shows how Scan command was met or not met.
   SNM SCAN Not Met 0 0 (also Good Complete)
   SME SCAN Met Equal 0 1
   SMNE SCAN Met Not Equal 1 0
- 4. Special Registers

R06 — This register contains the record number where the scan was met.
R14 — This register contains the MSB count and is decremented every 128 characters.

Length ( $\ell$ ) (D7-D5 of PAR 2)	Record Size	R14 = $2\ell$ - 1 at minimum reference flower of the (Initialize at Beginning of Record)

- R13 This register contains a modulo 128 LSB count which is initialized to 128 at beginning of each record. This count is decremented after each character is compared except for the last character in a pattern match situation.
- 5. The OFF<sub>H</sub> character in the key is treated as a don't care character position.
- 6. The Scan comparison is done on a byte by byte basis. That is, byte 1 of each field is compared to byte 1 of the key, byte 2 of each field is compared to byte 2 of the key, etc.

## 8272

8272

# SINGLE/DOUBLE DENSITY FLOPPY DISK CONTROLLER

- IBM Compatible in Both Single and Double Density Recording Formats
- Programmable Data Record Lengths: 128, 256, 512, or 1024 Bytes/Sector
- Multi-Sector and Multi-Track Transfer
   Capability
- Drive Up to 4 Floppy Disks
- Data Scan Capability Will Scan a Single Sector or an Entire Cylinder's Worth of Data Fields, Comparing on a Byte by Byte Basis, Data in the Processor's Memory with Data Read from the Diskette

- Data Transfers in DMA or Non-DMA Mode
- Parallel Seek Operations on Up to Four Drives
- Compatible with Most
   Microprocessors Including 8080A, 8085A, 8086 and 8088
- Single-Phase 8 MHz Clock
- Single +5 Volt Power Supply
- Available in 40-Pin Plastic Dual-in-Line Package

The 8272 is an LSI Floppy Disk Controller (FDC) Chip, which contains the circuitry and control functions for interfacing a processor to 4 Floppy Disk Drives. It is capable of supporting either IBM 3740 single density format (FM), or IBM System 34 Double Density format (MFM) including double sided recording. The 8272 provides control signals which simplify the design of an external phase locked loop, and write precompensation circuitry. The FDC simplifies and handles most of the burdens associated with implementing a Floppy Disk Drive Interface.

bytes to fully specify the operation which the processor wishes the FDC to perform. The following commands are available

Read Data	Write Data
Read ID	Format a Track
Read Deleted Data	Write Deleted Data
Read a Track	Seek
Scan Equal	Recalibrate (Restore to
Scan High or Equal	Track 0)
Scan Low or Equal	Sense Interrupt Status
Specify	Sense Drive Status

#### **FEATURES**

Address mark detection circuitry is internal to the FDC which simplifies the phase locked loop and read electronics. The track stepping rate, head load time, and head unload time may be programmed by the user. The 8272 offers many additional features such as multiple sector transfers in both read and write modes with a single command, and full IBM compatibility in both single (FM) and double density (MFM) modes.

# DESCRIPTION THE DAMA CONTROL OF THE STATE OF

Hand-shaking signals are provided in the 8272 which make DMA operation easy to incorporate with the aid of an external DMA Controller chip, such as the 8237. The FDC will operate in either DMA or Non-DMA mode. In the Non-DMA mode, the FDC generates interrupts to the processor for every transfer of a data byte between the CPU and the 8272. In the DMA mode, the processor need only load a command into the FDC and all data transfers occur under control of the 8272 and DMA controller.

There are 15 separate commands which the 8272 will execute. Each of these commands require multiple 8-bit

#### 8272 REGISTERS — CPU INTERFACE

The 8272 contains two registers which may be accessed by the main system processor; a Status Register and a Data Register. The 8-bit Main Status Register contains the status information of the FDC, and may be accessed at any time. The 8-bit Data Register (actually consists of several registers in a stack with only one register presented to the data bus at a time), stores data, commands, parameters, and FDD status information. Data bytes are read out of, or written into, the Data Register in order to program or obtain the results after execution of a command. The Status Register may only be read and is used to facilitate the transfer of data between the processor and 8272.

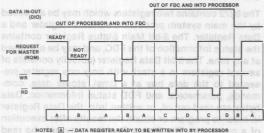

The relationship between the Status/Data registers and the signals RD, WR, and Ao is shown below.

A <sub>0</sub>	RD	WR	FUNCTION
0	0 obniv a	1 1 19	Read Main Status Register
0	and the same	0	Illegal
0	0	0 50	Illegal
1 hw	0	0	Illegal ne sur par
<b>1</b> M	00 o a a	fB1 1	Read from Data Register
110	visied wick	0	Write into Data Register

The bits in the Main Status Register are defined as

BIT NUMBER	NAME	SYMBOL	DESCRIPTION
DB <sub>0</sub>	FDD 0 Busy	D <sub>0</sub> B	FDD number 0 is in the Seek mode.
DB <sub>1</sub>	FDD 1 Busy	D <sub>1</sub> B	FDD number 1 is in the Seek mode.
DB <sub>2</sub>	FDD 2 Busy	D <sub>2</sub> B	FDD number 2 is in the Seek mode.
DB <sub>3</sub>	FDD 3 Busy	D <sub>3</sub> B	FDD number 3 is in the Seek mode.
DB <sub>4</sub>	FDC Busy	СВ	A read or write command is in process.
DB <sub>5</sub> als O	Non-DMA mode	NDM	The FDC is in the non-DMA mode. This bit is set only during the execution phase in non-DMA mode. Transition to "0" state indicates execution phase has ended.
DB <sub>6</sub> Butter 2 for	Data Input/Output	DIO	Indicates direction of data transfer between FDC and Data Register. If DIO = "1" then transfer is from Data Register to the Processor. If DIO = "0", then transfer is from the Processor to Data Register.
DB7 of I le been bi s emit bi the user. I the sebo	Request for Master	ROM PROPERTY OF THE PROPERTY O	Indicates Data Register is ready to send or receive data to or from the Processor. Both bits DIO and RQM should be used to perform the handshaking functions of "ready" and "direction" to the processor.

The DIO and RQM bits in the Status Register indicate when Data is ready and in which direction data will be transferred on the Data Bus.

DATA REGISTER NOT READY TO BE WRITTEN INTO BY PROCESSO - DATA REGISTER READY FOR NEXT DATA BYTE TO BE READ BY THE

D - DATA REGISTER NOT READY FOR NEXT DATA BYTE TO BE READ BY

STATUS REGISTER TIMING

The 8272 is capable of executing 15 different commands. Each command is initiated by a multi-byte transfer from the processor, and the result after execution of the command may also be a multi-byte transfer back to the processor. Because of this multi-byte interchange of information between the 8272 and the processor, it is convenient to consider each command as consisting of three phases:

Command Phase: The FDC receives all information

required to perform a particular operation from the processor.

Execution Phase: The FDC performs the operation it

was instructed to do.

Result Phase: After completion of the operation, status and other housekeeping in-

formation are made available to

the processor.

During Command or Result Phases the Main Status Register (described earlier) must be read by the processor before each byte of information is written into or read from the Data Register. Bits D6 and D7 in the Main Status Register must be in a 0 and 1 state, respectively, before each byte of the command word may be written into the 8272. Many of the commands require multiple bytes, and as a result the Main Status Register must be read prior to each byte transfer to the 8272. On the other hand, during the Result Phase, D6 and D7 in the Main Status Register must both be 1's (D6 = 1 and D7 = 1)before reading each byte from the Data Register. Note. this reading of the Main Status Register before each byte transfer to the 8272 is required in only the Command and Result Phases, and NOT during the Execution Phase.

During the Execution Phase, the Main Status Register need not be read. If the 8272 is in the Non-DMA Mode, then the receipt of each data byte (if 8272 is reading data from FDD) is indicated by an Interrupt signal on pin 18 (INT = 1). The generation of a Read signal (RD = 0) will reset the Interrupt as well as output the Data onto the Data Bus. For example, if the processor cannot handle Interrupts fast enough (every 13 µs for MFM mode) then it may poll the Main Status Register and then bit D7 (RQM) functions just like the Interrupt signal. If a Write

Command is in process then the WR signal performs the reset to the Interrupt signal.

If the 8272 is in the DMA Mode, no Interrupts are generated during the Execution Phase. The 8272 generates DRQ's (DMA Requests) when each byte of data is available. The DMA Controller responds to this request with both a  $\overline{DACK} = 0$  (DMA Acknowledge) and a  $\overline{RD} = 0$ (Read signal). When the DMA Acknowledge signal goes low (DACK = 0) then the DMA Request is reset (DRQ = 0). If a Write Command has been programmed then a WR signal will appear instead of RD. After the Execution Phase has been completed (Terminal Count has occurred) then an Interrupt will occur (INT = 1). This signifies the beginning of the Result Phase. When the first byte of data is read during the Result Phase, the Interrupt is automatically reset (INT = 0).

It is important to note that during the Result Phase all bytes shown in the Command Table must be read. The Read Data Command, for example, has seven bytes of

1-149

data in the Result Phase. All seven bytes must be read in order to successfully complete the Read Data Command. The 8272 will not accept a new command until all seven bytes have been read. Other commands may require fewer bytes to be read during the Result Phase.

The 8272 contains five Status Registers. The Main Status Register mentioned above may be read by the processor at any time. The other four Status Registers (ST0, ST1, ST2, and ST3) are only available during the Result Phase, and may be read only after successfully completing a command. The particular command which has been executed determines how many of the Status Registers will be read.

The bytes of data which are sent to the 8272 to form the Command Phase, and are read out of the 8272 in the Result Phase, must occur in the order shown in the Command Table. That is, the Command Code must be sent first and the other bytes sent in the prescribed sequence. No foreshortening of the Command or Result Phases are allowed. After the last byte of data in the Command Phase is sent to the 8272 the Execution Phase automatically starts. In a similar fashion, when

the last byte of data is read out in the Result Phase, the command is automatically ended and the 8272 is ready for a new command. A command may be aborted by simply sending a Terminal Count signal to pin 16 (TC = 1). This is a convenient means of ensuring that the processor may always get the 8272's attention even if the disk system hangs up in an abnormal manner.

#### **POLLING FEATURE OF THE 8272**

After the Specify command has been sent to the 8272, the Drive Select Lines DS0 and DS1 will automatically go into a polling mode. In between commands (and between step pulses in the SEEK command) the 8272 polls all four FDDs looking for a change in the Ready line from any of the drives. If the Ready line changes state (usually due to a door opening or closing) then the 8272 will generate an interrupt. When Status Register 0 (ST0) is read (after Sense Interrupt Status is issued), Not Ready (NR) will be indicated. The polling of the Ready line by the 8272 occurs continuously between instructions, thus notifying the processor which drives are on or off line.

**Table 3. Command Mnemonics** 

SYMBOL	NAME	DESCRIPTION
A <sub>0</sub>	Address Line 0	$A_0$ controls selection of Main Status Register ( $A_0 = 0$ ) or Data Register ( $A_0 = 1$ ).
C	Cylinder Number	C stands for the current selected Cylinder track number 0 through 76 of the medium.
D	Data OM OM	D stands for the data pattern which is going to be written into a Sector.
D <sub>7</sub> -D <sub>0</sub>	Data Bus	8-bit Data Bus where D <sub>7</sub> is the most significant bit, and D <sub>0</sub> is the least significant bit.
DS0, DS1	Drive Select	DS stands for a selected drive number 0 or 1.
DTL	Data Length	When N is defined as 00, DTL stands for the data length which users are going to read out or write into the Sector.
EOT 10	End of Track	EOT stands for the final Sector number of a Cylinder.
GPL	Gap Length	GPL stands for the length of Gap 3 (spacing between Sectors excluding VCO Sync Field).
Н	Head Address	H stands for head number 0 or 1, as specified in ID field.
HDS	Head Select	HDS stands for a selected head number 0 or 1 (H = HDS in all command words).
HLT :	Head Load Time	HLT stands for the head load time in the FDD (2 to 254 ms in 2 ms increments).
HUT	Head Unload Time	HUT stands for the head unload time after a read or write operation has occurred (16 to 240 ms in 16 ms increments).
MFM	FM or MFM Mode	If MF is low, FM mode is selected and if it is high, MFM mode is selected.
MT	Multi-Track	be performed (a cylinder under both HD0
N	Number	N stands for the number of data bytes written in a Sector.

COMMAND DESCRIPTION
---------------------

During the Command Phase, the Main Status Register must be polled by the CPU before each byte is written into the Data Register. The DIO (DB6) and RQM (DB7) bits in the Main Status Register must be in the "0" and "1" states respectively, before each byte of the command may be written into the 8272. The beginning of the execution phase for any of these commands will cause DIO and RQM to switch to "1" and "0" states respectively.

#### After writing data into the current sectoATAC CARR

A set of nine (9) byte words are required to place the FDC into the Read Data Mode. After the Read Data command has been issued the FDC loads the head (if it is in the unloaded state), waits the specified head settling time (defined in the Specify Command), and begins reading ID Address Marks and ID fields. When the current sector number ("R") stored in the ID Register (IDR)

SYMBOL	NAME	DESCRIPTION
NCN 39	New Cylinder Number	NCN stands for a new Cylinder number, which is going to be reached as a result of the Seek operation. Desired position of Head.
ND	Non-DMA Mode	ND stands for operation in the Non-DMA Mode.
PCN	Present Cylinder Number	PCN stands for the Cylinder number at the completion of SENSE INTERRUPT STATUS Command. Position of Head at present time.
Ranij	Record yed steb e	R stands for the Sector number, which will be read or written.
R/W	Read/Write	R/W stands for either Read (R) or Write (W) signal.
SC mad	Sector	SC indicates the number of Sectors per Cylinder.
SK	Skip gainsom	SK stands for Skip Deleted Data Address Mark.
SRT Daga en	Step Rate Time	SRT stands for the Stepping Rate for the FDD (1 to 16 ms in 1 ms increments). The same Stepping Rate applies to all drives (F=1 ms, E=2 ms, etc.).
ST 0 ST 1 ST 2 ST 3	Status 0 Status 1 Status 2 Status 3	ST 0-3 stand for one of four registers which store the status information after a command has been executed. This information is available during the result phase after command execution. These registers should not be confused with the main status register (selected by $A_0\!=\!0$ ). ST 0-3 may be read only after a command has been executed and contain information relevant to that particular command.
STP polibolit i itaa OG (doleh t	ole twice withou "R"), then the F	During a Scan operation, if STP = 1, the data in contiguous sectors is compared byte by byte with data sent from the processor (or DMA), and if STP = 2, then alternate sectors are read and compared.

compares with the sector number read off the diskette, then the FDC outputs data (from the data field) byte-bybyte to the main system via the data bus.

After completion of the read operation from the current sector, the Sector Number is incremented by one, and the data from the next sector is read and output on the data bus. This continuous read function is called a "Multi-Sector Read Operation." The Read Data Command may be terminated by the receipt of a Terminal Count signal. Upon receipt of this signal, the FDC stops outputting data to the processor, but will continue to read data from the current sector, check CRC (Cyclic Redundancy Count) bytes, and then at the end of the sector terminate the Read Data Command.

The amount of data which can be handled with a single command to the FDC depends upon MT (multi-track), MFM (MFM/FM), and N (Number of Bytes/Sector). Table 4 below shows the Transfer Capacity.

expend has notices note to bleit OI and ab Table 4. Transfer Capacity

Multi-Track	MFM/FM MFM	Bytes/Sector N	Maximum Transfer Capacity (Bytes/Sector) (Number of Sectors)	Final Sector Read from Diskette

0 00 F0ag	bnii10	02 03	(512) (8) = 4,096 (1024) (8) = 8,192	8 at Side 0 or 8 at Side 1
1 1	esta)(sta	Q 0 02 QM	(512) (16) = 8,192 (1024) (16) = 16,384	8 at Side 1

The "multi-track" function (MT) allows the FDC to read data from both sides of the diskette. For a particular cylinder, data will be transferred starting at Sector 1, Side 0 and completing at Sector L, Side 1 (Sector L = last sector on the side). Note, this function pertains to only one cylinder (the same track) on each side of the diskette

When N = 0, then DTL defines the data length which the FDC must treat as a sector. If DTL is smaller than the actual data length in a Sector, the data beyond DTL in the Sector, is not sent to the Data Bus. The FDC reads (internally) the complete Sector performing the CRC check, and depending upon the manner of command termination, may perform a Multi-Sector Read Operation. When N is non-zero, then DTL has no meaning and should be set to 0FFH.

At the completion of the Read Data Command, the head is not unloaded until after Head Unload Time Interval (specified in the Specify Command) has elapsed. If the processor issues another command before the head unloads then the head settling time may be saved between subsequent reads. This time out is particularly valuable when a diskette is copied from one drive to another.

If the FDC detects the Index Hole twice without finding the right sector, (indicated in "R"), then the FDC sets the ND (No Data) flag in Status Register 1 to a 1 (high), and terminates the Read Data Command. (Status Register 0 also has bits 7 and 6 set to 0 and 1 respectively.)

After reading the ID and Data Fields in each sector, the FDC checks the CRC bytes. If a read error is detected (incorrect CRC in ID field), the FDC sets the DE (Data Error) flag in Status Register 1 to a 1 (high), and if a CRC error occurs in the Data Field the FDC also sets the DD (Data Error in Data Field) flag in Status Register 2 to a 1 (high), and terminates the Read Data Command. (Status Register 0 also has bits 7 and 6 set to 0 and 1 respectively.)

If the FDC reads a Deleted Data Address Mark off the diskette, and the SK bit (bit D5 in the first Command Word) is not set (SK = 0), then the FDC sets the CM (Control Mark) flag in Status Register 2 to a 1 (high), and terminates the Read Data Command, after reading all the data in the Sector. If SK = 1, the FDC skips the sector with the Deleted Data Address Mark and reads the next sector.

During disk data transfers between the FDC and the processor, via the data bus, the FDC must be serviced by the processor every  $27~\mu s$  in the FM Mode, and every  $13~\mu s$  in the MFM Mode, or the FDC sets the OR (Over Run) flag in Status Register 1 to a 1 (high), and terminates the Read Data Command.

If the processor terminates a read (or write) operation in the FDC, then the ID Information in the Result Phase is dependent upon the state of the MT bit and EOT byte. Table 5 shows the values for C, H, R, and N, when the processor terminates the Command.

Table 5. ID Information When Processor
Terminates Command

AT 100	A) reseig	Final Sector Transferred to		ID Information at Result Phase

Notes: 1. NC (No Change): The same value as the one at the beginning of command

LSB (Least Significant Bit): The least significant bit of H is complemented.

#### WRITE DATA

A set of nine (9) bytes are required to set the FDC into the Write Data mode. After the Write Data command has been issued the FDC loads the head (if it is in the unloaded state), waits the specified head settling time (defined in the Specify Command), and begins reading ID Fields. When the current sector number ("R"), stored in the ID Register (IDR) compares with the sector number read off the diskette, then the FDC takes data from the processor byte-by-byte via the data bus, and outputs it to the FDD.

After writing data into the current sector, the Sector Number stored in "R" is incremented by one, and the next data field is written into. The FDC continues this "Multi-Sector Write Operation" until the issuance of a Terminal Count signal. If a Terminal Count signal is sent to the FDC it continues writing into the current sector to complete the data field. If the Terminal Count signal is received while a data field is being written then the remainder of the data field is filled with 00 (zeros).

The FDC reads the ID field of each sector and checks the CRC bytes. If the FDC detects a read error (incorrect CRC) in one of the ID Fields, it sets the DE (Data Error) flag of Status Register 1 to a 1 (high), and terminates the Write Data Command. (Status Register 0 also has bits 7 and 6 set to 0 and 1 respectively.)

The Write Command operates in much the same manner as the Read Command. The following items are the same; refer to the Read Data Command for details:

- Transfer Capacity
- · EN (End of Cylinder) Flag
- ND (No Data) Flag

- Head Unload Time Interval () 918 and heatile mental.
- . ID Information when the processor terminates command (see Table 2)
- Definition of DTL when N = 0 and when N ≠ 0

In the Write Data mode, data transfers between the processor and FDC must occur every 31 us in the FM mode. and every 15 us in the MFM mode. If the time interval between data transfers is longer than this then the FDC sets the OR (Over Run) flag in Status Register 1 to a 1 (high), and terminates the Write Data Command.

#### sector 20, then the Scan Com ATAC CETTING

This command is the same as the Write Data Command except a Deleted Data Address Mark is written at the beginning of the Data Field instead of the normal Data Address Mark.

# READ DELETED DATA all ni tee pall (nun tevo) Ao

This command is the same as the Read Data Command except that when the FDC detects a Data Address Mark at the beginning of a Data Field (and SK = 0 (low)), it will read all the data in the sector and set the CM flag in Status Register 2 to a 1 (high), and then terminate the command. If SK = 1, then the FDC skips the sector with the Data Address Mark and reads the next sector.

which is the current head position w XXART A DASH This command is similar to READ DATA Command except that the entire data field is read continuously from each of the sectors of a track. Immediately after encountering the INDEX HOLE, the FDC starts reading all data fields on the track as continuous blocks of data. If the FDC finds an error in the ID or DATA CRC check bytes, it continues to read data from the track. The FDC compares the ID information read from each sector with the value stored in the IDR, and sets the ND flag of Status Register 1 to a 1 (high) if there is no comparison. Multi-track or skip operations are not allowed with this against PCN, and when NCN = PCN, then chammoo is

This command terminates when EOT number of sectors have been read. If the FDC does not find an ID Address Mark on the diskette after it encounters the INDEX HOLE for the second time, then it sets the MA (missing address mark) flag in Status Register 1 to a 1 (high), and terminates the command. (Status Register 0 has bits 7 and 6 set to 0 and 1 respectively.)

#### **READ ID**

The READ ID Command is used to give the present position of the recording head. The FDC stores the values from the first ID Field it is able to read. If no proper ID Address Mark is found on the diskette, before the IN-DEX HOLE is encountered for the second time then the MA (Missing Address Mark) flag in Status Register 1 is set to a 1 (high), and if no data is found then the ND (No Data) flag is also set in Status Register 1 to a 1 (high) and the command is terminated.

whole sector of data is compared, if the conditions are

# FORMAT A TRACK and at number of the sector number o

The Format Command allows an entire track to be formatted. After the INDEX HOLE is detected. Data is written on the Diskette: Gaps, Address Marks, ID Fields and Data Fields, all per the IBM System 34 (Double Density) or System 3740 (Single Density) Format are recorded. The particular format which will be written is controlled by the values programmed into N (number of bytes/sector), SC (sectors/cylinder), GPL (Gap Length), and D (Data Pattern) which are supplied by the processor during the Command Phase. The Data Field is filled with the Byte of data stored in D. The ID Field for each sector is supplied by the processor; that is, four data requests per sector are made by the FDC for C (Cylinder Number), H (Head Number), R (Sector Number) and N (Number of Bytes/Sector). This allows the diskette to be formatted with nonsequential sector numbers, if desired.

After formatting each sector, the processor must send new values for C, H, R, and N to the 8272 for each sector on the track. The contents of the R register is incremented by one after each sector is formatted, thus, the R register contains a value of R+1 when it is read during the Result Phase. This incrementing and formatting continues for the whole track until the FDC encounters the INDEX HOLE for the second time, whereupon it terminates the command.

If a FAULT signal is received from the FDD at the end of a write operation, then the FDC sets the EC flag of Status Register 0 to a 1 (high), and terminates the command after setting bits 7 and 6 of Status Register 0 to 0 and 1 respectively. Also the loss of a READY signal at the beginning of a command execution phase causes if the FDC encounters a Delete.notination.

Table 6 shows the relationship between N. SC. and GPL for various sector sizes: and no notose tast ent as not

Table 6. Sector Size Relationships

FORMAT	SECTOR SIZE	N	sc	GPL <sup>1</sup>	GPL <sup>2</sup>	REMARKS

order to show that a I

#### SCAN COMMANDS

The SCAN Commands allow data which is being read from the diskette to be compared against data which is being supplied from the main system (Processor in NON-DMA mode, and DMA Controller in DMA mode). The FDC compares the data on a byte-by-byte basis, and looks for a sector of data which meets the conditions of D<sub>FDD</sub> = D<sub>Processor</sub>, D<sub>FDD</sub> ≤ D<sub>Processor</sub>, or D<sub>FDD</sub> ≥ D<sub>Processor</sub>. Ones complement arithmetic is used for comparison (FF = largest number, 00 = smallest number). After a whole sector of data is compared, if the conditions are not met, the sector number is incremented (R+STP → R), and the scan operation is continued. The scan operation continues until one of the following conditions occur: the conditions for scan are met (equal, low, or high). the last sector on the track is reached (EOT), or the terminal count signal is received.

If the conditions for scan are met then the FDC sets the SH (Scan Hit) flag of Status Register 2 to a 1 (high), and terminates the Scan Command. If the conditions for scan are not met between the starting sector (as specified by R) and the last sector on the cylinder (EOT), then the FDC sets the SN (Scan Not Satisfied) flag of Status Register 2 to a 1 (high), and terminates the Scan Command. The receipt of a TERMINAL COUNT signal from the Processor or DMA Controller during the scan operation will cause the FDC to complete the comparison of the particular byte which is in process, and then to terminate the command. Table 7 shows the status of bits SH and SN under various conditions of SCAN.

Table 7. Scan Status Codes

	STATUS R	EGISTER 2	COMMENTS	
COMMAND	BIT 2 = SN	BIT 3 = SH		
corld tures, who	0	BRY MOFE	D <sub>FDD</sub> = D <sub>Processor</sub>	
Scan Equal	Janean e	100 1011 36	DFDD # DProcessor	
FDB at the end	0	wiends of t	D <sub>FDD</sub> = D <sub>Processor</sub>	
Scan Low or Equal	0	0	D <sub>FDD</sub> < D <sub>Processor</sub>	
den ma em ei	50 c4 1 5	0 1	D <sub>FDD</sub> < D <sub>Processor</sub> D <sub>FDD</sub> ≰ D <sub>Processor</sub>	
O BIU BBIRNINI	0	DO LA COLO	D <sub>FDD</sub> = D <sub>Processor</sub>	
Scan High or Equal	818 0 3 51	8 7 0 0 0	D <sub>FDD</sub> > D <sub>Processor</sub>	
ennie YOARR	to Inches	0	D <sub>FDD</sub> > D <sub>Processor</sub> D <sub>FDD</sub> ≱ D <sub>Processor</sub>	

If the FDC encounters a Deleted Data Address Mark on one of the sectors (and SK=0), then it regards the sector as the last sector on the cylinder, sets CM (Control Mark) flag of Status Register 2 to a 1 (high) and terminates the command. If SK=1, the FDC skips the sector with the Deleted Address Mark, and reads the next sector. In the second case (SK=1), the FDC sets the CM (Control Mark) flag of Status Register 2 to a 1 (high) in order to show that a Deleted Sector had been encountered.

When either the STP (contiguous sectors STP=01, or alternate sectors STP=02 sectors are read) or the MT (Multi-Track) are programmed, it is necessary to remember that the last sector on the track must be read. For example, if STP=02, MT=0, the sectors are numbered sequentially 1 through 26, and we start the Scan Command at sector 21; the following will happen. Sectors 21, 23, and 25 will be read, then the next sector (26) will be skipped and the Index Hole will be encountered before the EOT value of 26 can be read. This will result in an abnormal termination of the command. If the EOT had been set at 25 or the scanning started at sector 20, then the Scan Command would be completed in a normal manner.

During the Scan Command data is supplied by either the processor or DMA Controller for comparison against the data read from the diskette. In order to avoid having the OR (Over Run) flag set in Status Register 1, it is necessary to have the data available in less than 27  $\mu$ s (FM Mode) or 13  $\mu$ s (MFM Mode). If an Overrun occurs the FDC terminates the command.

### read all the data in the sector and set the Chiffso In Status Register 2 to a 1 (high), and then termin/ABB/s

The read/write head within the FDD is moved from cylinder to cylinder under control of the Seek Command. The FDC compares the PCN (Present Cylinder Number) which is the current head position with the NCN (New Cylinder Number), and performs the following operation if there is a difference:

PCN < NCN: Direction signal to FDD set to a 1 (high), and Step Pulses are issued. (Step In.)

PCN > NCN: Direction signal to FDD set to a 0 (low), and Step Pulses are issued. (Step Out.)

The rate at which Step Pulses are issued is controlled by SRT (Stepping Rate Time) in the SPECIFY Command. After each Step Pulse is issued NCN is compared against PCN, and when NCN = PCN, then the SE (Seek End) flag is set in Status Register 0 to a 1 (high), and the command is terminated.

During the Command Phase of the Seek operation the FDC is in the FDC BUSY state, but during the Execution Phase it is in the NON BUSY state. While the FDC is in the NON BUSY state, another Seek Command may be issued, and in this manner parallel seek operations may be done on up to 4 Drives at once.

If an FDD is in a NOT READY state at the beginning of the command execution phase or during the seek operation, then the NR (NOT READY) flag is set in Status Register 0 to a 1 (high), and the command is terminated.

#### RECALIBRATE

This command causes the read/write head within the FDD to retract to the Track 0 position. The FDC clears the contents of the PCN counter, and checks the status of the Track 0 signal from the FDD. As long as the Track 0 signal is low, the Direction signal remains 1 (high) and Step Pulses are issued. When the Track 0 signal goes high, the SE (SEEK END) flag in Status Register 0 is set to a 1 (high) and the command is terminated. If the Track 0 signal is still low after 77 Step Pulses have been issued, the FDC sets the SE (SEEK END) and EC (EQUIP-MENT CHECK) flags of Status Register 0 to both 1s (highs), and terminates the command.

The ability to overlap RECALIBRATE Commands to multiple FDDs, and the loss of the READY signal, as described in the SEEK Command, also applies to the RECALIBRATE Command.

#### **SENSE INTERRUPT STATUS**

An Interrupt signal is generated by the FDC for one of the following reasons:

- 1. Upon entering the Result Phase of:
  - a. Read Data Command
  - b. Read a Track Command
  - c. Read ID Command
  - d. Read Deleted Data Command
  - e. Write Data Command
  - f. Format a Cylinder Command
  - g. Write Deleted Data Command
  - h. Scan Commands
- 2. Ready Line of FDD changes state
- 3. End of Seek or Recalibrate Command
- 4. During Execution Phase in the NON-DMA Mode

Interrupts caused by reasons 1 and 4 above occur during normal command operations and are easily discernible by the processor. However, interrupts caused by reasons 2 and 3 above may be uniquely identified with the aid of the Sense Interrupt Status Command. This command when issued resets the interrupt signal and via bits 5, 6, and 7 of Status Register 0 identifies the cause of the interrupt.

Table 8. Seek, Interrupt Codes

SEEK END	INTERR	UPT CODE	YH I Bauti PY		
BIT 5	BIT 6	BIT 7	CAUSE		
o dicate the cotected signal		This bit is	Ready Line changed state, either polarity		
1 icate the statu rom the FDD.	DD. 0	fromone I	Normal Termination of Seek or Recalibrate Command		
icate tits statu from the FDD icate the statu	isingia 0 st	anT out to	Abnormal Termination of Seek or Recalibrate Command		

Neither the Seek or Recalibrate Command have a Result Phase. Therefore, it is mandatory to use the Sense Interrupt Status Command after these commands to effectively terminate them and to provide verification of the head position (PCN).

#### SPECIFY

The Specify Command sets the initial values for each of the three internal timers. The HUT (Head Unload Time) defines the time from the end of the Execution Phase of one of the Read/Write Commands to the head unload state. This timer is programmable from 16 to 240 ms in increments of 16 ms (01 = 16 ms, 02 = 32 ms . . . . OF = 240 ms). The SRT (Step Rate Time) defines the time interval between adjacent step pulses. This timer is programmable from 1 to 16 ms in increments of 1 ms (F = 1 ms, E = 2 ms, D = 3 ms, etc.). The HLT (Head Load Time) defines the time between when the Head Load signal goes high and when the Read/Write operation starts. This timer is programmable from 2 to 254 ms in increments of 2 ms (01 = 2 ms, 02 = 4 ms, 03 = 6 ms . . . . . FE = 254 ms).

The time intervals mentioned above are a direct function of the clock (CLK on pin 19). Times indicated above are for an 8 MHz clock, if the clock was reduced to 4 MHz (mini-floppy application) then all time intervals are increased by a factor of 2.

The choice of DMA or NON-DMA operation is made by the ND (NON-DMA) bit. When this bit is high (ND = 1) the NON-DMA mode is selected, and when ND = 0 the DMA mode is selected.

#### SENSE DRIVE STATUS

This command may be used by the processor whenever it wishes to obtain the status of the FDDs. Status Register 3 contains the Drive Status information.

### INVALID tes al gall eint rebnity

If an invalid command is sent to the FDC (a command not defined above), then the FDC will terminate the command. No interrupt is generated by the 8272 during this condition. Bit 6 and bit 7 (DIO and RQM) in the Main Status Register are both high ("1") indicating to the processor that the 8272 is in the Result Phase and the contents of Status Register 0 (STO) must be read. When the processor reads Status Register 0 it will find a 80H indicating an invalid command was received.

A Sense Interrupt Status Command must be sent after a Seek or Recalibrate interrupt, otherwise the FDC will consider the next command to be an Invalid Command.

In some applications the user may wish to use this command as a No-Op command, to place the FDC in a standby or no operation state.

  Internal or External Character
  Synchronization; Automatic Sync
  Insertion
- Asynchronous 5–8 Bit Characters; Clock Rate—1, 16 or 64 Times Baud Rate; Break Character Generation; 1, 1½, or 2 Stop Bits; False Start Bit Detection; Automatic Break Detect and Handling
- Synchronous Baud Rate—DC to 64K Baud

- Asynchronous Baud Rate—DC to 19.2K Baud
- Full-Duplex, Double-Buffered
  Transmitter and Receiver
- Error Detection—Parity, Overrun and Framing
- Compatible with an Extended Range of Intel Microprocessors
- 28-Pin DIP Package antercoon At 258 on T
- All Inputs and Outputs are TTL box 1858 Compatible
- Single +5V Supply
- Single TTL Clock 1970 elduck and A1538

The Intel® 8251A is the enhanced version of the industry standard, Intel 8251 Universal Synchronous/ Asynchronous Receiver/Transmitter (USART), designed for data communications with Intel's microprocessor families such as MCS-68, 80, 85, and iAPX-86, 88. The 8251A is used as a peripheral device and is programmed by the CPU to operate using virtually any serial data transmission technique presently in use (including IBM "bi-sync"). The USART accepts data characters from the CPU in parallel format and then converts them into a continuous serial data stream for transmission. Simultaneously, it can receive serial data streams and convert them into parallel data characters for the CPU. The USART will signal the CPU whenever it can accept a new character for transmission or whenever it has received a character for the CPU. The CPU can read the complete status of the USART at any time. These include data transmission errors and control signals such as SYNDET, TxEMPTY. The chip is fabricated using N-channel silicon gate technology.

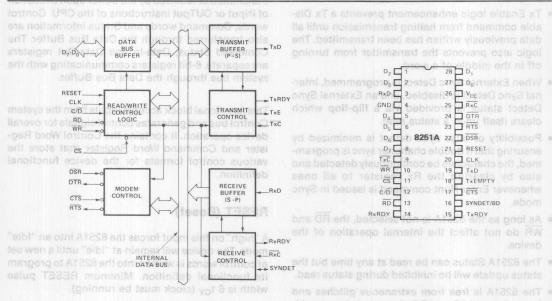

Figure 1. Block Diagram

Figure 2. Pin Configuration

#### **FEATURES AND ENHANCEMENTS**

The 8251A is an advanced design of the industry standard USART, the Intel® 8251. The 8251A operates with an extended range of Intel microprocessors and maintains compatibility with the 8251. Familiarization time is minimal because of compatibility and involves only knowing the additional features and enhancements, and reviewing the AC and DC specifications of the 8251A.

The 8251A incorporates all the key features of the 8251 and has the following additional features and enhancements:

8251A has double-buffered data paths with separate I/O registers for control, status, Data In, and Data Out, which considerably simplifies control programming and minimizes CPU overhead.

Vicque +5V Supply

- In asynchronous operations, the Receiver detects and handles "break" automatically, relieving the CPU of this task.
- A refined Rx initialization prevents the Receiver from starting when in "break" state, preventing unwanted interrupts from a disconnected USART.
- At the conclusion of a transmission, TxD line will always return to the marking state unless SBRK is programmed.
- Tx Enable logic enhancement prevents a Tx Disable command from halting transmission until all data previously written has been transmitted. The logic also prevents the transmitter from turning off in the middle of a word.
- When External Sync Detect is programmed, Internal Sync Detect is disabled, and an External Sync Detect status is provided via a flip-flop which clears itself upon a status read.
- Possibility of false sync detect is minimized by ensuring that if double character sync is programmed, the characters be contiguously detected and also by clearing the Rx register to all ones whenever Enter Hunt command is issued in Sync mode.
- As long as the 8251A is not selected, the RD and WR do not affect the internal operation of the device.
- The 8251A Status can be read at any time but the status update will be inhibited during status read.
- The 8251A is free from extraneous glitches and has enhanced AC and DC characteristics, providing higher speed and better operating margins.
- Synchronous Baud rate from DC to 64K.

#### **FUNCTIONAL DESCRIPTION**

#### General

The 8251A is a Universal Synchronous/Asynchronous Receiver/Transmitter designed for a wide range of Intel microcomputers such as 8048, 8080, 8085, 8086 and 8088. Like other I/O devices in a microcomputer system, its functional configuration is programmed by the system's software for maximum flexibility. The 8251A can support most serial data techniques in use, including IBM "bi-sync."

In a communication environment an interface device must convert parallel format system data into serial format for transmission and convert incoming serial format data into parallel system data for reception. The interface device must also delete or insert bits or characters that are functionally unique to the communication technique. In essence, the interface should appear "transparent" to the CPU, a simple input or output of byte-oriented system data.

#### **Data Bus Buffer**

This 3-state, bidirectional, 8-bit buffer is used to interface the 8251A to the system Data Bus. Data is transmitted or received by the buffer upon execution of INput or OUTput instructions of the CPU. Control words, Command words and Status information are also transferred through the Data Bus Buffer. The Command Status, Data-In and Data-Out registers are separate, 8-bit registers communicating with the system bus through the Data Bus Buffer.

This functional block accepts inputs from the system Control bus and generates control signals for overall device operation. It contains the Control Word Register and Command Word Register that store the various control formats for the device functional definition.

## **RESET (Reset)**

A "high" on this input forces the 8251A into an "Idle" mode. The device will remain at "Idle" until a new set of control words is written into the 8251A to program its functional definition. Minimum RESET pulse width is 6  $t_{\rm CY}$  (clock must be running).

A command reset operation also puts the device into the "Idle" state.

Figure 1. Block Diagram

## CLK (Clock)

The CLK input is used to generate internal device timing and is normally connected to the Phase 2 (TTL) output of the Clock Generator. No external inputs or outputs are referenced to CLK but the frequency of CLK must be greater than 30 times the Receiver or Transmitter data bit rates.

## WR (Write)

A "low" on this input informs the 8251A that the CPU is writing data or control words to the 8251A.

## RD (Read)

A "low" on this input informs the 8251A that the CPU is reading data or status information from the 8251A.

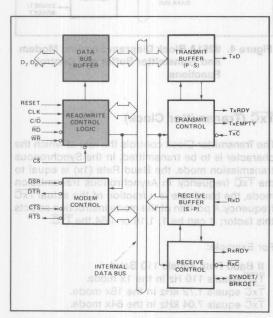

Figure 3. 8251A Block Diagram Showing Data
Bus Buffer and Read/Write Logic
Functions

	C/D	RD	WR	CS	
113	0	0	1	0	8251A DATA → DATA BUS
	0	1010	0	0	DATA BUS → 8251A DATA
	1110	0	DIMON	0	STATUS ⇒ DATA BUS
	101 er	1 1	0,5	0	DATA BUS ⇒ CONTROL
	X	olo bis	allor	0	DATA BUS ⇒ 3-STATE
	X	X	X	1	DATA BUS ⇒ 3-STATE

## C/D (Control/Data)

This input, in conjunction with the WR and RD inputs, informs the 8251A that the word on the Data Bus is either a data character, control word or status information.

1 = CONTROL/STATUS; 0 = DATA.

## CS (Chip Select) dene gnied dogu notezimenent

A "low" on this input selects the 8251A. No reading or writing will occur unless the device is selected. When  $\overline{CS}$  is high, the Data Bus is in the float state and  $\overline{RD}$  and  $\overline{WR}$  have no effect on the chip.

#### **Modem Control**

The 8251A has a set of control inputs and outputs that can be used to simplify the interface to almost any modem. The modem control signals are general purpose in nature and can be used for functions other than modem control, if necessary.

## DSR (Data Set Ready)

The DSR input signal is a general-purpose, 1-bit inverting input port. Its condition can be tested by the CPU using a Status Read operation. The DSR input is normally used to test modem conditions such as Data Set Ready.

### DTR (Data Terminal Ready)

The DTR output signal is a general-purpose, 1-bit inverting output port. It can be set "low" by programming the appropriate bit in the Command Instruction word. The DTR output signal is normally used for modem control such as Data Terminal Ready.

## RTS (Request to Send)

The RTS output signal is a general-purpose, 1-bit inverting output port. It can be set "low" by programming the appropriate bit in the Command Instruction word. The RTS output signal is normally used for modem control such as Request to Send.

## CTS (Clear to Send)

A "low" on this input enables the 8251A to transmit serial data if the Tx Enable bit in the Command byte is set to a "one." If either a Tx Enable off or CTS off condition occurs while the Tx is in operation, the Tx will transmit all the data in the USART, written prior to Tx Disable command before shutting down.

C/D (Control/Data)

#### **Transmitter Buffer**

The Transmitter Buffer accepts parallel data from the Data Bus Buffer, converts it to a serial bit stream, inserts the appropriate characters or bits (based on the communication technique) and outputs a composite serial stream of data on the TxD output pin on the falling edge of TxC. The transmitter will begin transmission upon being enabled if  $\overline{\text{CTS}} = 0$ . The TxD line will be held in the marking state immediately upon a master Reset or when Tx Enable or  $\overline{\text{CTS}}$  is off or the transmitter is empty.

## Transmitter Control

The Transmitter Control manages all activities associated with the transmission of serial data. It accepts and issues signals both externally and internally to accomplish this function.

# TxRDY (Transmitter Ready)

This output signals the CPU that the transmitter is ready to accept a data character. The TxRDY output pin can be used as an interrupt to the system, since it is masked by TxEnable; or, for Polled operation, the CPU can check TxRDY using a Status Read operation. TxRDY is automatically reset by the leading edge of WR when a data character is loaded from the CPU.

Note that when using the Polled operation, the TxRDY status bit is *not* masked by TxEnable, but will only indicate the Empty/Full Status of the Tx Data Input Register.

## TxE (Transmitter Empty)

When the 8251A has no characters to send, the TxEMPTY output will go "high." It resets upon receiving a character from the CPU if the transmitter is enabled. TxEMPTY remains low when the transmitter is disabled even if it is actually empty. TxEMPTY can be used to indicate the end of a transmission mode, so that the CPU "knows" when to "turn the line around" in the half-duplex operational mode.

In the Synchronous mode, a "high" on this output indicates that a character has not been loaded and the SYNC character or characters are about to be or are being transmitted automatically as "fillers." TXEMPTY does not go low when the SYNC characters are being shifted out.

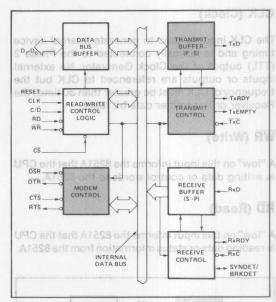

Figure 4. 8251A Block Diagram Showing Modem and Transmitter Buffer and Control Functions

## TxC (Transmitter Clock)

The Transmitter Clock controls the rate at which the character is to be transmitted. In the Synchronous transmission mode, the Baud Rate (1x) is equal to the TxC frequency. In Asynchronous transmission mode, the baud rate is a fraction of the actual TxC frequency. A portion of the mode instruction selects this factor; it can be 1, 1/16 or 1/64 the TxC.

#### For Example:

If Baud Rate equals 110 Baud,

TxC equals 110 Hz in the 1x mode.

TxC equals 1.72 kHz in the 16x mode.

TxC equals 7.04 kHz in the 64x mode.

The falling edge of  $\overline{\text{TxC}}$  shifts the serial data out of the 8251A.

#### Receiver Buffer

The Receiver accepts serial data, converts this serial input to parallel format, checks for bits or characters that are unique to the communication technique and sends an "assembled" character to the CPU. Serial data is input to RxD pin, and is clocked in on the rising edge of  $\overline{\text{RxC}}$ .

# intel

## Receiver Control MOITAREGO GELHATEG

This functional block manages all receiver-related activities which consists of the following features.

The RxD initialization circuit prevents the 8251A from mistaking an unused input line for an active low data line in the "break condition." Before starting to receive serial characters on the RxD line, a valid "1" must first be detected after a chip master Reset. Once this has been determined, a search for a valid low (Start bit) is enabled. This feature is only active in the asynchronous mode, and is only done once for each master Reset.

The False Start bit detection circuit prevents false starts due to a transient noise spike by first detecting the falling edge and then strobing the nominal center of the Start bit (RxD = low).

Parity error detection sets the corresponding status bit. ed. D. ArdS8 edition represents a same

The Framing Error status bit is set if the Stop bit is absent at the end of the data byte (asynchronous mode).

## RxRDY (Receiver Ready) on a notion transform

This output indicates that the 8251A contains a character that is ready to be input to the CPU. RxRDY can be connected to the interrupt structure of the CPU or, for polled operation, the CPU can check the condition of RxRDY using a Status Read operation.

RxEnable, when off, holds RxRDY in the Reset Condition. For Asynchronous mode, to set RxRDY, the Receiver must be enabled to sense a Start Bit and a complete character must be assembled and transferred to the Data Output Register. For Synchronous mode, to set RxRDY, the Receiver must be enabled and a character must finish assembly and be transferred to the Data Output Register.

Failure to read the received character from the Rx Data Output Register prior to the assembly of the next Rx Data character will set overrun condition error and the previous character will be written over and lost. If the Rx Data is being read by the CPU when the internal transfer is occurring, overrun error will be set and the old character will be lost.

## RxC (Receiver Clock) 100 OMY2) TEGMY2

The Receiver Clock controls the rate at which the character is to be received. In Synchronous Mode, the Baud Rate (1x) is equal to the actual frequency of RxC. In Asynchronous Mode, the Baud Rate is a fraction of the actual RxC frequency. A portion of the mode instruction selects this factor: 1, 1/16 or 1/64 the RxC.

SYNC character in the Receive mode. If seeme SYNC

Baud Rate equals 300 Baud, if

RxC equals 300 Hz in the 1x mode;

RxC equals 4800 Hz in the 16x mode;

RxC equals 19.2 kHz in the 64x mode.

Baud Rate equals 2400 Baud, if

RxC equals 2400 Hz in the 1x mode;

RxC equals 38.4 kHz in the 16x mode;

RxC equals 153.6 kHz in the 64x mode.

Data is sampled into the 8251A on the rising edge of  $\overline{\text{RxC}}$ .

NOTE: In most communications systems, the 8251A will be handling both the transmission and reception operations of a single link. Consequently, the Receive and Transmit Baud Rates will be the same. Both TxC and RxC will require identical frequencies for this operation and can be tied together and connected to a single frequency source (Baud Rate Generator) to simplify the interface.

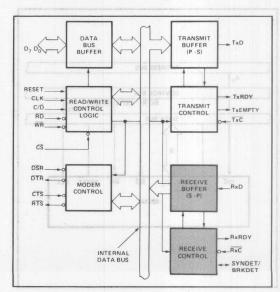

Figure 5. 8251A Block Diagram Showing
Receiver Buffer and Control Functions

# SYNDET (SYNC Detect/ of Taylogo R) OXA BRKDET Break Detect)

This pin is used in Synchronous Mode for SYN-DET and may be used as either input or output, programmable through the Control Word. It is reset to output mode low upon RESET. When used as an output (internal Sync mode), the SYNDET pin will go "high" to indicate that the 8251A has located the SYNC character in the Receive mode. If the 8251A is programmed to use double Sync characters (bisync), then SYNDET will go "high" in the middle of the last bit of the second Sync character. SYNDET is automatically reset upon a Status Read operation.

The Receiver Clock controls the rate at which the

When used as an input (external SYNC detect mode), a positive going signal will cause the 8251A to start assembling data characters on the rising edge of the next RxC. Once in SYNC, the "high" input signal can be removed. When External SYNC Detect is programmed, Internal SYNC Detect is disabled.

## **BREAK (Async Mode Only)**

This output will go high whenever the receiver remains low through two consecutive stop bit sequences (including the start bits, data bits, and parity bits). Break Detect may also be read as a Status bit. It is reset only upon a master chip Reset or Rx Data returning to a "one" state.

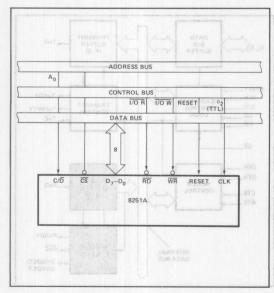

Figure 6. 8251A Interface to 8080 Standard
System Bus

## DETAILED OPERATION DESCRIPTION

# General polyolios of the following

The complete functional definition of the 8251A is programmed by the system's software. A set of control words must be sent out by the CPU to initialize the 8251A to support the desired communications format. These control words will program the: BAUD RATE, CHARACTER LENGTH, NUMBER OF STOP BITS, SYNCHRONOUS or ASYNCHRONOUS OPERATION, EVEN/ODD/OFF PARITY, etc. In the Synchronous Mode, options are also provided to select either internal or external character synchronization.

Once programmed, the 8251A is ready to perform its communication functions. The TxRDY output is raised "high" to signal the CPU that the 8251A is ready to receive a data character from the CPU. This output (TxRDY) is reset automatically when the CPU writes a character into the 8251A. On the other hand, the 8251A receives serial data from the MODEM or I/O device. Upon receiving an entire character, the RxRDY output is raised "high" to signal the CPU that the 8251A has a complete character ready for the CPU to fetch. RxRDY is reset automatically upon the CPU data read operation.

The 8251A cannot begin transmission until the Tx Enable (Transmitter Enable) bit is set in the Command Instruction and it has received a Clear To Send (CTS) input. The TxD output will be held in the marking state upon Reset.

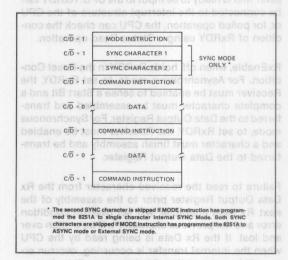

Figure 7. Typical Data Block

## Programming the 8251A of augmontance

Prior to starting data transmission or reception, the 8251A must be loaded with a set of control words generated by the CPU. These control signals define the complete functional definition of the 8251A and must immediately follow a Reset operation (internal or external).

The control words are split into two formats:

- 1. Mode Instruction as and epivorg for secon USO
- 2. Command Instruction T A 238 and enoted and

# Mode Instruction Www (about released Divine

This instruction defines the general operational characteristics of the 8251A. It must follow a Reset operation (internal or external). Once the Mode Instruction has been written into the 8251A by the CPU, SYNC characters or Command Instructions may be written.

#### Command Instruction

This instruction defines a word that is used to control the actual operation of the 8251A.

Both the Mode and Command Instructions must conform to a specified sequence for proper device operation (see Figure 7). The Mode Instruction must be written immediately following a Reset operation, prior to using the 8251A for data communication.

All control words written into the 8251A after the Mode Instruction will load the Command Instruction. Command Instructions can be written into the 8251A at any time in the data block during the operation of the 8251A. To return to the Mode Instruction format, the master Reset bit in the Command Instruction word can be set to initiate an internal Reset operation which automatically places the 8251A back into the Mode Instruction format. Command Instructions must follow the Mode Instructions or Sync characters.

# To abbum and to bestant if divining ent to album and Mode Instruction Definition and stab tast and

The 8251A can be used for either Asynchronous or Synchronous data communication. To understand how the Mode Instruction defines the functional operation of the 8251A, the designer can best view the device as two separate components, one Asynchronous and the other Synchronous, sharing

the same package. The format definition can be changed only after a master chip Reset. For explanation purposes the two formats will be isolated.

NOTE: When parity is enabled it is not considered as one of the data bits for the purpose of programming the word length. The actual parity bit received on the Rx Data line cannot be read on the Data Bus. In the case of a programmed character length of less than 8 bits, the least significant Data Bus bits will hold the data; unused bits are "don't care" when writing data to the 8251A, and will be "zeros" when reading the data from the 8251A.

## Asynchronous Mode (Transmission)

Whenever a data character is sent by the CPU the 8251A automatically adds a Start bit (low level) followed by the data bits (least significant bit first), and the programmed number of Stop bits to each character. Also, an even or odd Parity bit is inserted prior to the Stop bit(s), as defined by the Mode Instruction. The character is then transmitted as a serial data stream on the TxD output. The serial data is shifted out on the falling edge of TxC at a rate equal to 1, 1/16, or 1/64 that of the TxC, as defined by the Mode Instruction. BREAK characters can be continuously sent to the TxD if commanded to do so.

When no data characters have been loaded into the 8251A the TxD output reamins "high" (marking) unless a Break (continuously low) has been programmed.

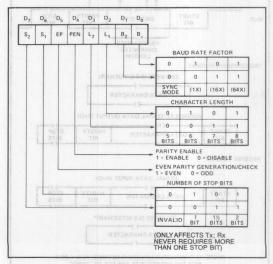

Figure 8. Mode Instruction Format,
Asynchronous Mode

# l<sub>g</sub>ini

#### Asynchronous Mode (Receive)

The RxD line is normally high. A falling edge on this line triggers the beginning of a START bit. The validity of this START bit is checked by again strobing this bit at its nominal center (16X or 64X mode only). If a low is detected again, it is a valid START bit. and the bit counter will start counting. The bit counter thus locates the center of the data bits, the parity bit (if it exists) and the stop bits. If parity error occurs, the parity error flag is set. Data and parity bits are sampled on the RxD pin with the rising edge of RxC. If a low level is detected as the STOP bit, the Framing Error flag will be set. The STOP bit signals the end of a character. Note that the receiver reguires only one stop bit, regardless of the number of stop bits programmed. This character is then loaded into the parallel I/O buffer of the 8251A. The RxRDY pin is raised to signal the CPU that a character is ready to be fetched. If a previous character has not been fetched by the CPU, the present character replaces it in the I/O buffer, and the OVERRUN Error flag is raised (thus the previous character is lost). All of the error flags can be reset by an Error Reset Instruction. The occurrence of any of these errors will not affect the operation of the 8251A.

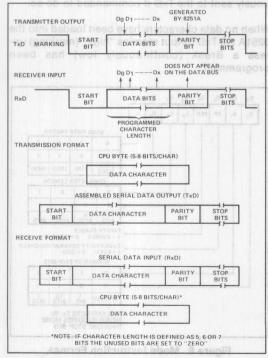

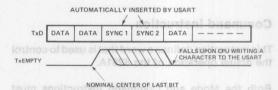

Figure 9. Asynchronous Mode

#### Synchronous Mode (Transmission)

The TxD output is continuously high until the CPU sends its first character to the 8251A which usually is a SYNC character. When the CTS line goes low, the first character is serially transmitted out. All characters are shifted out on the falling edge of TxC. Data is shifted out at the same rate as the TxC.

Once transmission has started, the data stream at the TxD output must continue at the  $\overline{\text{TxC}}$  rate. If the CPU does not provide the 8251A with a data character before the 8251A Transmitter Buffers become empty, the SYNC characters (or character if in single SYNC character mode) will be automatically inserted in the TxD data stream. In this case, the TxEMPTY pin is raised high to signal that the 8251A is empty and SYNC characters are being sent out. TxEMPTY does not go low when the SYNC is being shifted out (see figure below). The TxEMPTY pin is internally reset by a data character being written into the 8251A.

#### Synchronous Mode (Receive)

In this mode, character synchronization can be internally or externally achieved. If the SYNC mode has been programmed, ENTER HUNT command should be included in the first command instruction word written. Data on the RxD pin is then sampled on the rising edge of RxC. The content of the Rx buffer is compared at every bit boundary with the first SYNC character until a match occurs. If the 8251A has been programmed for two SYNC characters, the subsequent received character is also compared; when both SYNC characters have been detected, the USARTends the HUNT mode and is in character synchronization. The SYNDET pin is then set high, and is reset automatically by a STATUS READ. If parity is programmed, SYNDET will not be set until the middle of the parity bit instead of the middle of the last data bit. "offining noticurtent should

In the external SYNC mode, synchronization is achieved by applying a high level on the SYNDET pin, thus forcing the 8251A out of the HUNT mode. The high level can be removed after one RXC cycle. An ENTER HUNT command has no effect in the asynchronous mode of operation.

letni

Parity error and overrun error are both checked in the same way as in the Asynchronous Rx mode. Parity is checked when not in Hunt, regardless of whether the Receiver is enabled or not.

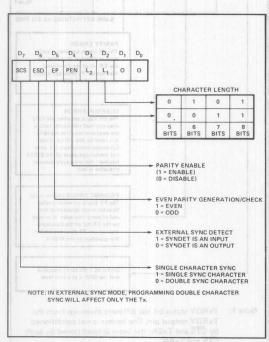

Figure 10. Mode Instruction Format,
Synchronous Mode

The CPU can command the receiver to enter the HUNT mode if synchronization is lost. This will also set all the used character bits in the buffer to a "one," thus preventing a possible false SYNDET caused by data that happens to be in the Rx Buffer at ENTER HUNT time. Note that the SYNDET F/F is reset at each Status Read, regardless of whether internal or external SYNC has been programmed. This does not cause the 8251A to return to the HUNT mode. When in SYNC mode, but not in HUNT, Sync Detection is still functional, but only occurs at the "known" word boundaries. Thus, if one Status Read indicates SYNDET and a second Status Read also indicates SYNDET, then the programmed SYNDET characters have been received since the previous Status Read. (If double character sync has been programmed, then both sync characters have been contiguously received to gate a SYNDET indication.) When external SYNDET mode is selected, internal Sync Detect is disabled, and the SYNDET F/F may be set at any bit boundary. - 00 January

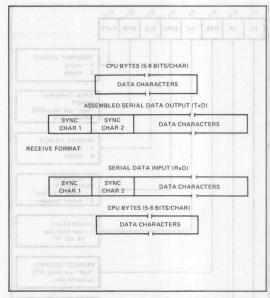

Figure 11. Data Format, Synchronous Mode

#### **COMMAND INSTRUCTION DEFINITION**

Once the functional definition of the 8251A has been programmed by the Mode Instruction and the sync characters are loaded (if in Sync Mode) then the device is ready to be used for data communication. The Command Instruction controls the actual operation of the selected format. Functions such as: Enable Transmit/Receive, Error Reset and Modem Controls are provided by the Command Instruction.

Once the Mode Instruction has been written into the 8251A and Sync characters inserted, if necessary, then all further "control writes" (C/D = 1) will load a Command Instruction. A Reset Operation (internal or external) will return the 8251A to the Mode Instruction format.

#### Note: Internal Reset on Power-up

When power is first applied, the 8251A may come up in the Mode, Sync character or Command format. To guarantee that the device is in the Command Instruction format before the Reset command is issued, it is safest to execute the worst-case initialization sequence (sync mode with two sync characters). Loading three 00Hs consecutively into the device with  $C/\bar{D}=1$  configures sync operation and writes two dummy 00H sync characters. An Internal Reset command (40H) may then be issued to return the device to the "Idle" state.

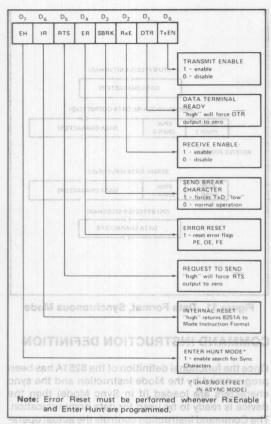

Figure 12. Command Instruction Format

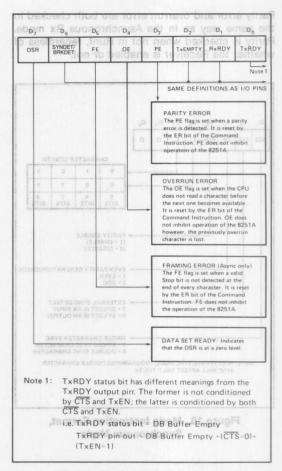

#### STATUS READ DEFINITION

In data communication systems it is often necessary to examine the "status" of the active device to ascertain if errors have occurred or other conditions that require the processor's attention. The 8251A has facilities that allow the programmer to "read" the status of the device at any time during the functional operation. (Status update is inhibited during status read.)

A normal "read" command is issued by the CPU with  $C/\overline{D}=1$  to accomplish this function,

Some of the bits in the Status Read Format have identical meanings to external output pins so that the 8251A can be used in a completely polled or interrupt-driven environment. TxRDY is an exception.

Note that status update can have a maximum delay of 28 clock periods from the actual event affecting the status.

The CPU tamed bean Reatless (1914) This will also HUNT mode it synchronization is lost. This will also

- Programmable System Clock to 1 × , 2 x , 3 x , or 5 x 1.024 MHz

The Intel® 8256 Multifunction Universal Asynchronous Receiver-Transmitter (MUART) combines five commonly used functions into a single 40-pin device. It is designed to interface to the 8048, 8085A, iAPX 86, and iAPX 88 to perform serial communications, parallel I/O, timing, event counting, and priority interrupt functions. All of these functions are fully programmable through nine internal registers. In addition, the five timer/counters and two parallel I/O ports can be accessed directly by the microprocessor.

A single negative-going pulse causes the transmission of a single previously loaded character out of the transmitter buffer. If this pulse occurs when the buffer is empty or during the transmission of a character up to 0.5 of the first stop bit, it will be ignored. If a baud rate from 1-0F <sub>16</sub> is selected, $\overline{\text{CTS}}$ must be low for at least 1/32 of a bit, or it will be ignored.

#### **FUNCTIONAL DESCRIPTION**

The 8256 Multi-Function Universal Asynchronous Receiver-Transmitter (MUART) combines five commonly used functions onto a single 40-pin device. The MUART performs asynchronous serial communications, parallel I/O, timing, event counting, and interrupt control.

#### Serial Communications

The serial communications portion of the MUART contains a full-duplex asynchronous receiver-transmitter (UART). A programmable baud rate generator is included on the MUART to permit a variety of operating speeds without external components. The UART can be programmed by the CPU for a variety of character sizes, parity generation and detection, error detection, and start/stop bit handling. The receiver checks the start and stop bits in the center of the bit, and a break halts the reception of data. The transmitter can send breaks and can be controlled by an external enable pin.

#### Parallel I/O

The MUART includes 16 bits of general purpose parallel I/O. Eight bits (Port 1) can be individually changed from input to output or used for special I/O functions. The other eight bits (Port 2) can be used as nibbles (4 bits) or as bytes. These eight bits also include a handshaking capability using two pins on Port 1.

#### Counter/Timers

There are five 8-bit counter/timers on the MUART. The timers can be programmed to use either a 1kHz or 16kHz clock generated from the system clock. Four of the 8-bit counter/timers can be cascaded to two 16-bit counter/timers, and one of the 8-bit counter/timers can be reset to its initial value by an external signal.

#### Interrupts

An eight-level priority interrupt controller can be configured for fully nested or normal interrupt priority. Seven of the eight interrupts service functions on the MUART (counter/timers, UART), and one external interrupt is provided which can be used for a particular function or for chaining interrupt controllers or more MUARTs. The MUART will support 8085 and 8086/88 systems with direct interrupt vectoring, or the MUART can be polled to determine the cause of the interrupt.

#### **Command Register 1**

#### FRQ — Timer Frequency Select

This bit selects between two frequencies for the five timers. If FRQ = 0, the timer input frequency is  $16\,\text{kHz}$  (62.5  $\mu$ s). If FRQ = 1, the timer input frequency is  $1\,\text{kHz}$  (1 ms). The selected clock frequency is shared by all the counter/timers enabled for timing; thus, all timers must run with the same time base.

#### 8086 - 8086 Mode Enable

This bit selects between 8048/8085 mode and 8086/8088 mode. In 8085 mode (8086 = 0), A0 to A3 are used to address the internal registers, and an RST instruction is generated in response to the first  $\overline{\text{INTA}}$ . In 8086 mode (8086 = 1), A1 to A4 are used to address the internal registers, and A0 is used as an extra chip select (A0 must equal zero to be enabled). The response to  $\overline{\text{INTA}}$  is for 8086 interrupts where the first  $\overline{\text{INTA}}$  is ignored, and an interrupt vector (40<sub>16</sub> to 47<sub>16</sub>) is placed on the bus in response to the second  $\overline{\text{INTA}}$ .

#### BITI - Interrupt on Bit Change

This bit disables the Timer 2 interrupt and enables an interrupt when a low-to-high transition occurs on pin 7 of Port 1 (pin 32).

#### BRKI - Break-in Detect Enable

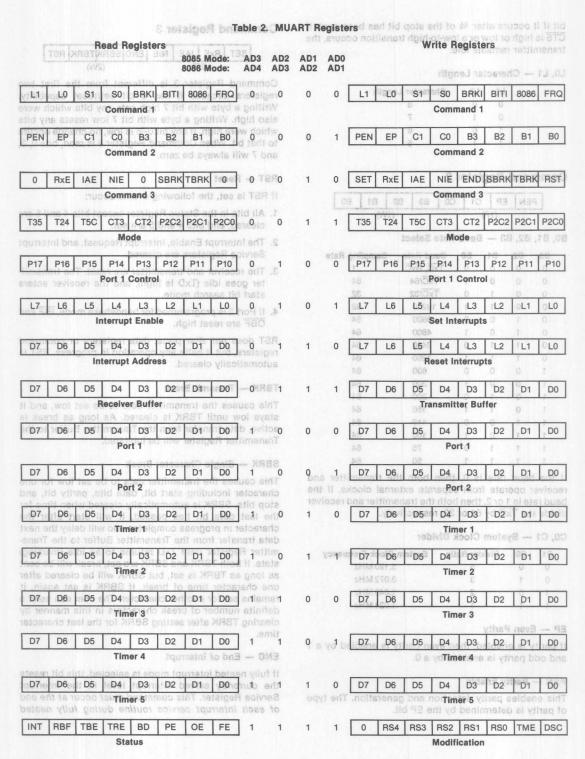

This bit enables the break-in detect feature. A break-in is detected when pin 6 of Port 1 (pin 33) is low during the first stop bit of a transmitted character. This could be used to detect a break-in condition by connecting the serial transmission line to pin 33. A break-in detect is OR-ed with break detect in bit 3 of the Status Register. If  $\overline{\text{RxC}}$  and  $\overline{\text{TxC}}$  are used for the serial bit rates, break-in cannot be detected.

#### S0, S1 - Stop Bit Length

ength

If 0.75 stop bits is selected,  $\overline{\text{CTS}}$  becomes edge sensitive rather than level sensitive. A high-to-low transition of  $\overline{\text{CTS}}$  immediately initiates the transmission of the next character. A high-to-low transition will be ignored if the transmit buffer is empty, or if it occurs before 0.75 of the first stop bit. It will shorten the stop

bit if it occurs after 34 of the stop bit has been sent. If Command Register 3 CTS is high or low or a low-to-high transition occurs, the transmitter remains idle.

#### L0. L1 - Character Length

L1a	LO	Character	Length	1
0	0	8	<u> </u>	
0	1	7		
 1.1	0	6	100	
1	1	5		

#### **Command Register 2**

#### B0. B1. B2. B3 - Baud Rate Select

В3	B2	B1	В0	<b>Baud Rate</b>	Sa	mpling	Rate
010	0	0	0	TxC, RxC	01.4	1	
0	0	0	Cpstn	TxC/64		64	
0	0	1	0	TxC/32		32	
0.0	0	5.1	8.1	19200		32	
0	1	0	0	9600		64	
0	1	0	1	4800		64	
0.0	1	2.1	0	2400		64	
0	1	1	1	1200	(continues or	64	
1	0	0	0	600		64	
001	0	0	.1	300		64	
1	0	1	0	200	U/1.2	64	
1	0	1	18 707	150		64	
1	-1-	0	0	110		- 64	
901	1	0	91	100		64	
1	1	1	0	75		64	
1_	1	1	1	50		64	
			mark &				

If the baud rate is 0, then both the transmitter and receiver operate from separate external clocks. If the baud rate is 1 or 2, then both the transmitter and receiver divide the TxC by 64 or 32, respectively.

#### C0, C1 - System Clock Divider

C1	CO	Divider Ratio	System Clock Frequency
0	0	5	5.120 MHz
0	1	3	3.072 MHz
1	0	2	2.048 MHz
1041	-1	20 1 20 1 50	1.024 MHz

#### EP - Even Parity

If parity is enabled, then even parity is enabled by a 1 and odd parity is enabled by a 0.

#### PEN - Parity Enable

This enables parity detection and generation. The type of parity is determined by the EP bit.

	_		_	-	1	-		
	SET	RxE	IAE	NIE	END	SBRK	TBRK	RST
3.0	1.0	(2	R)			(2)	W)	

Command Register 3 is different from the first two registers because it has a bit set/reset capability. Writing a byte with bit 7 high sets any bits which were also high. Writing a byte with bit 7 low resets any bits which were high. If any bit 0-6 is low, no change occurs to that bit. When Command Register 3 is read, bits 0, 3, and 7 will always be zero.

#### RST - Reset DIRETDIRES O JAM LAN LOVE

If RST is set, the following events occur:

- 1. All bits in the Status Register except bits 4 and 5 are cleared, and bits 4 and 5 are set.
- 2. The Interrupt Enable, Interrupt Request, and Interrupt Service Registers are cleared.
- 3. The receiver and transmitter are reset. The transmitter goes idle (TxD is high), and the receiver enters start bit search mode.
- 4. If Port 2 is programmed for handshake mode, IBF and OBF are reset high.

RST does not alter ports, data registers or command registers, but it halts any operation in progress. RST is automatically cleared.

#### TBRK — Transmit Break

This causes the transmitter data to be set low, and it stays low until TBRK is cleared. As long as break is active, data transfer from the Transmitter Buffer to the Transmitter Register will be inhibited.

#### SBRK - Single Character Break

This causes the transmitter data to be set low for one character including start bit, data bits, parity bit, and stop bits. SBRK is automatically cleared when time for the last data bit has passed. It will start after the character in progress completes and will delay the next data transfer from the Transmitter Buffer to the Transmitter Register until TxD returns to an idle (marking) state. If both TBRK and SBRK are set, break will be sent as long as TBRK is set, but SBRK will be cleared after one character time of break. If SBRK is set again, it remains set for another character. The user can send a definite number of break characters in this manner by clearing TBRK after setting SBRK for the last character

#### END — End of Interrupt

If fully nested interrupt mode is selected, this bit resets the currently served interrupt level in the Interrupt Service Register. This command must occur at the end of each interrupt service routine during fully nested

interrupt mode. END is automatically cleared when the Interrupt Service Register (internal) is cleared. See the NIE description for more information on nested interrupt servicing. END is ignored if nested interrupts are not enabled.

# NIE - Nested Interrupt Enable

This bit enables fully nested interrupts. In this mode, the service routine for a lower priority interrupt can be interrupted by a request from a higher priority task.

In fully nested interrupt mode, INTA or reading the Interrupt Address Register resets the highest priority interrupt bit in the Interrupt Register (internal), sets the corresponding bit in the Interrupt Service Register (internal), and resets INT. If an interrupt of higher priority than the currently served interrupt is requested or the END bit is set while another interrupt request is pending, the INT line will go high again. If an interrupt service routine is interrupted by an interrupt of higher priority, two or more bits in the Interrupt Service Register will be set.

If NIE is low, interrupt priority is used only when two interrupts occur at the same time. INT will be high as long as the CPU has not responded to all the interrupts in the Interrupt Register.

#### IAE - Interrupt Acknowledge Enable

This bit enables an automatic response to INTA. The particular response is determined by the 8086 bit in Command Register 1.

#### RxE — Receiver Enable

This bit enables the serial receiver. The Receiver Buffer and all receiver status information will be disabled except for the break detect status.

# SET — Bit Set/Reset

If this bit is high during a write to Command Register 3, then any bit marked by a high will be set. If this bit is low, then any bit marked by a high will be cleared.

#### **Mode Register**

T35	T24	T5C	СТЗ	CT2	P2C2	P2C1	P2C0
	(3	R)			(3)	W)	
						an L	777

#### P2C2, P2C1, P2C0 — Port 2 Control

			Writinoistan 2 sets the datain
P2C2			Mode of the Upper of policower
ed Oalu	P002p	0.80	de nibble di ste input stote input
0.0	ento o	contents	nibble of input and output
0	1	0	nibble output input
0	1	1	nibble output output
1	0	0	byte handshake input
1	0	1	byte handshake output
1	1	0	DO NOT USE
1	1	1	test

If test mode is selected and BRG of Port 1 Control Register is set, then the output from the internal baud rate generator is placed on pin 4 of Port 1 (pin 35).

# CT2. CT3 — Counter/Timer Mode

If CT2 or CT3 are high, then counter/timer 2 or 3 respectively is configured as an event counter on pin 2 or 3 respectively of Port 1 (pins 37 or 36). The event counter decrements the count by one on each low-to-high transition of the external input. If CT2 or CT3 is low, then the respective counter/timer is configured as a timer and the Port 1 pins are used for parallel I/O.

#### T5C - Timer 5 Control

If T5C is set, then Timer 5 can be preset and started by an external signal. Writing to the Timer 5 Register loads the Timer 5 Save Register and stops the timer. A high-to-low transition on pin 5 of Port 1 (pin 34) loads the timer with the saved value and starts the timer. The next high-to-low transition on pin 5 retriggers the timer by reloading it with the initial value and continues timing.

When the timer reaches zero it issues an interrupt request, disables its interrupt level and continues counting. A subsequent high-to-low transition on pin 5 resets Timer 5 to its initial value. For another timer interrupt, the Timer 5 interrupt enable bit must be set again.

#### T35, T24 — Cascade Timers Mggl sirth nedt it retained

These two bits cascade Timers 3 and 5 or 2 and 4. Timers 2 and 3 are the lower bytes, while Timers 4 and 5 are the upper bytes. If T5C is set, then both Timers 3 and 5 can be preset and started by an external pulse. When a high-to-low transition occurs, Timer 5 is preset to its saved value, but Timer 3 is always preset to all ones. If either CT2 or CT3 is set, then the corresponding timer pair is a 16-bit event counter.

#### **Port 1 Control Register**

act. I	100	ert 1	201	501	750	Lan I	501
P17	P16	P15	P14	P13	P12	P11	P10
	(4	R)			(4)	W)	

Receiver and Transmitter

Each bit in the Port 1 Control Register configures the direction of the corresponding pin. If the bit is high, the pin is an output, and if it is low the pin is an input. Every Port 1 pin has another function which is controlled by other registers. If that special function is disabled, the pin functions as a general I/O pin as specified by this register. The special functions for each pin are described below.

# Port 10, 11 - Handshake Control

If byte handshake control is enabled for Port 2 by the Mode Register, then Port 10 is programmed as STB/ACK handshake control input and Port 11 is programmed as IBF/OBF handshake control output.

If byte handshake mode is enabled for output on Port 2, OBF indicates that a character has been loaded into the

Port 2 output buffer. When an external device reads the data, it acknowledges this operation by driving ACK low.

OBF is set low by writing to Port 2 and is reset high by ACK.

If byte handshake mode is enabled for input on Port 2, STB is an input to the MUART to latch the data into Port 2. After the data is latched, IBF is driven low. IBF is reset high when Port 2 is read.

#### Port 12, 13 - Counter 2, 3 Input

If Timer 2 or Timer 3 is programmed as an event counter by the mode register, then Port 12 or 13 is the counter input for Event Counter 2 or 3, respectively.

#### Port 14 — Baud Rate Generator Output Clock

If test mode is enabled by the Mode Register and Command Register 2 baud rate select is greater than 2, then Port 14 is an output from the internal baud rate generator.

# Port 15 — Timer 5 Trigger Visitini entrally it pubsoles

If T5C is set in the Mode Register enabling a retriggerable timer, then Port 15 is the input which starts and reloads Timer 5.

# Port 16 - Break-in Detect

If break-in detect is enabled by BRKI in Command Register 1, then this input is used to sense a break-in. If Port 16 is low while the serial transmitter is sending the last stop bit, then a break-in condition is signaled.

#### Port 17 — Port Interrupt Source

If BITI in Command Register 1 is set, then a low-to-high transition on Port 17 generates an interrupt request on priority level 1.

#### **Receiver and Transmitter Buffer**

Both the transmitter and the receiver in the MUART are fully double buffered. The Receiver Buffer full flag is cleared when the character is read. If the character is not read before the next character's first stop bit, then an overrun error is generated. Bytes written to the Transmitter Buffer are held until the Transmitter Register (internal) is empty. If the Transmitter Register is empty, the byte is transferred immediately and the Transmitter Buffer empty flag is set. If a serial character length is less than 8 bits, then the unused most significant bits are set to zero on a read and are ignored on a write.

#### Port Aw bersels vilselfametus al OVE sbom touvietel

Writing to Port 1 sets the data in the Port 1 output latch. Writing to an input pin does not affect the pin, but the data is stored and will be output if the direction of the pin is changed later. If the pin is used as a control signal, the pin will not be affected, but the data is stored. Reading Port 1 transfers the data in Port 1 onto the data bus. Reading an output pin or a control pin puts the data in the output latch (not the control signal) onto the data bus.

#### Interrupt Enable Register

priority than the currently served interrupt is requested

Interrupts are enabled by writing to the Set Interrupts Register (5W). Interrupts are disabled by writing to the Reset Interrupts Register (6W). Each bit set by the Set Interrupts Register (5W) will enable that level interrupt, and each bit set in the Reset Interrupts Register (6W) will disable that level interrupt. The user can determine which interrupts are enabled by reading the Interrupt Enable Register (5R).

Priority	Source
Highest L0	Timer 1
L1	Timer 2 or Port Interrupt
	External Interrupt (EXTINT)
ib ad Iliw L30	Timer 3 or Timers 3 & 5
L4	Receiver Interrupt
L5	Transmitter Interrupt
L6	Timer 4 or Timers 2 & 4
	Timer 5 or 2 and 3 d and 1 limer 5 or 2 limer 5 limer 5 or 2 limer 5 limer 5 limer 5 or 2 limer 5 limer

#### Port 259 1059 5059 5TO | ETO

Writing to Port 2 sets the data in the Port 2 output latch. Writing to an input pin does not affect the pin, but it does store the data in the latch. Reading Port 2 puts the input pins onto the bus or the contents of the output latch for output pins.

#### Timer 1-5

Reading Timer N puts the contents of the timer onto the data bus. If the counter changes while RD is low, the value on the data bus will not change. If two timers are cascaded, reading the high order byte will cause the low order byte to be latched. Reading the low order byte will unlatch them both. Writing to either timer or decascading them also clears the latch condition. Writing to a timer sets the starting value of that timer. If two timers are cascaded, writing to the high order byte presets the low order byte to all ones. Loading only the high order byte with a value of X leads to a count of X · 256 + 255. Timers count down continuously. If the interrupt is enabled, it occurs when the counter changes from 1 to 0. When the interrupt is set in the Interrupt Register, interrupts are disabled in the Interrupt Mask Register.

#### **Status Register**

#### FE — Framing Error, Transmission Mode

If transmission mode is disabled (in Modification Register), then FE indicates a framing error. A framing error is detected during the *first* stop bit. The error is reset by reading the Status Register or by a chip reset. A framing error does not inhibit the loading of the Receiver Buffer. If RXD remains low, the receiver will assemble the next character. The false stop bit is treated as the next start bit, and no high-to-low transition on RxD is required to synchronize the receiver.

If transmission mode is enabled, then this bit is used to suggest the transmitter was sending. FE will be high if the transmitter is active during the reception of the parity bit (or last data bit for no-parity). It is reset if the transmitter is not active or by a chip reset. The bit is intended to imply that the received character is from the transmitter in half-duplex systems.

#### OE - Overrun Error

If the user does not read the character in the Receiver Buffer before the next character is received and transferred to this register, then the OE bit is set. The OE flag is set during the reception of the first stop bit and is cleared when the Status Register is read or when a chip reset occurs.

#### PE — Parity Error

A parity error is set during the first stop bit and is reset by reading the Status Register or by a chip reset.

#### BD - Break Detect, Break-in Detect

If BRKI in Command Register 1 is set to enable break-in detect, then BD indicates a break-in condition. If Port 16 is low during the transmission of the last stop bit, then BD will be set near the end of the last stop bit. Break-in detect can only be detected if the internal baud rate generator is used. Break-in remains set until the Status Register is read or the chip is reset.

If BRKI is low, then BD indicates a break condition on the receiver. BD is set when the first stop bit of a break is sampled and will remain set until the Status Register is read or the chip is reset. The receiver will remain idle until the next high-to-low transition on RxD. A detected break inhibits the loading of the Receiver Buffer.

#### TRE — Transmitter Register Empty

This status bit indicates that the Transmitter Register is busy. It is set by a chip reset and when the last stop bit has left the transmitter. It is reset when a character is loaded into the Transmitter Register. If  $\overline{CTS}$  is low, the Transmitter Register will be loaded during the transmission of the start bit. If  $\overline{CTS}$  is high at the end of a character, TRE will remain high and no character will be loaded into the Transmitter Register until  $\overline{CTS}$  goes low. If the transmitter was inactive before a character is loaded into the Transmitter Buffer, the Transmitter Register will be empty temporarily while the buffer is full. However, the data in the buffer will be transferred to the transmitter register immediately and TRE will be cleared while TBE is set.

#### TBE — Transmitter Buffer Empty

TBE indicates the Transmitter Buffer is empty and is ready to accept a character. TBE is set by a chip reset or the transfer of data to the Transmitter Register and is cleared when a character is written to the transmitter buffer.

#### RBF — Receiver Buffer Full

RBF is set when the Receiver Buffer has been loaded with a new character during the sampling of the first stop bit. RBF is cleared by reading the receiver buffer or by a chip reset.

#### INT - Interrupt Pending

The INT bit reflects the state of the INT pin (pin 15) and indicates an interrupt is pending in the Interrupt Register. It is reset by INTA or by reading the Interrupt Address Register if only one interrupt is pending and by a chip reset.

FE, OE, PE, RBF, and break detect all generate a level 4 interrupt when the receiver samples the first stop bit. TRE, TBE, and break-in detect generate a level 5 interrupt. TRE generates an interrupt when TBE is set and the Transmitter Register finishes transmitting. The

break-in detect interrupt is issued at the same time as TBE or TRE.

#### **Modification Register**

0	RS4	RS3	RS2	RS1	RS0	TME	DS
---	-----	-----	-----	-----	-----	-----	----

#### DSC — Disable Start Bit Check

DSC disables the receiver's start bit check. In this state the receiver will not be reset if RxD is not low at the center of the start bit. This function is disabled by a chip reset. So A .0x8 no notification working it xxm and time.

#### TME — Transmission Mode Enable

TME enables transmission mode and disables framing error detection. A chip reset disables transmission mode and enables framing error detection.

#### RS0, RS1, RS2, RS3, RS4 - Receiver Sample Time

The number in RSn alters when the receiver samples RxD. A chip reset sets this value to 0 which is the center

loaded into the hansmitter Register until C1's goes low. If the transmitter was inactive before a character is loaded into the Transmitter Buffer, the Transmitter Register will be empty temporarily while the buffer is full. However, the data in the buffer will be transfered to the transmitter register immediately and TRE will be cleared while TBE is set.

#### 18E - Transmitter Suffer Emply

TRE indicates the Transmitter Buffer Is empty and is ready to accept a character. TBE is set by a chip reset or the transmitter Register and is the transmit when a character is written to the transmitter buffer.

#### REF - Receiver Buffer Full

RBF is set when the Receiver Buffer has been loaded with a new character during the sampling of the first stop bit. RBF is cleared by reading the receiver buffer or by a chip reset.

#### naihang inumatal .... 748

The INT bit reflects the state of the INT pin (pin 15) and indicates an interrupt is pending in the interrupt indicates. It is reset by INTA or by reading the interrupt Address Register if only one interrupt is pending and by a chirt reset.

FE, OE, PE, RBF, and break dated all generate a level 4 interrupt when the receiver samples the first stop bit. TRE, TBE, and break-in detect generate a level 5 interrupt. TRE generates an interrupt when TBE is set and the Transmitter Register (injahes transmitting. The

of the bit (sample time 字句: The receiver is not clocked by RxC.

1	0	0	0	32	31		

#### FF -- Framing Error, Transmission Mode

If transmission mode is disabled (in Modification Register), then FE indicates a framing error. A framing error is detected during the II/st stop bit. The error is reset by reading the Status Register or by a chip reset. A framing error does not inhibit the loading of the Receiver Buffer. If RXD remains low, the receiver will assemble the next character. The false stop bit is treated as the next start bit, and no high-to-low transition on RXD is required to exceptionize the receiver.

If transmission mode is enabled, then this bit is used to suggest the transmitter was sending. PE will be high if the transmitter is active during the reception of the parity bit (or last data bit for no-parity). It is reset if the transmitter is not active or by a chip neset. The bit is intended to imply that the received character is from the transmitter is half-during systems.

#### No. - Overme Error

If the user does not read the character in the Receiver Buffer before the next character is received and transferred to this register, then the OE bit is sat. The OE flag is set during the reception of the first stop bit and is cleared when the Status Register is read or when a chiral set of the character.

#### PE -- Parity Error

A parity error is set during the first stop bit and is reset by reading the Status Register or by a chip reset.

# 8273, 8273-4, 8273-8 PROGRAMMABLE HDLC/SDLC PROTOCOL CONTROLLER

- **CCITT X.25 Compatible**
- **HDLC/SDLC Compatible**
- Full Duplex, Half Duplex, or Loop SDLC Operation
- Up to 64K Baud Synchronous Transfers
- Automatic FCS (CRC) Generation and Checking
- Up to 9.6K Baud with On-Board Phase Locked Loop

- Programmable NRZI Encode/Decode
- Two User Programmable Modem Control Ports
- Digital Phase Locked Loop Clock Recovery
- Minimum CPU Overhead
- Fully Compatible with 8048/8080/8085/ 8088/8086 CPUs
- Single +5V Supply

The Intel® 8273 Programmable HDLC/SDLC Protocol Controller is a dedicated device designed to support the ISO/CCITT's HDLC and IBM's SDLC communication line protocols. It is fully compatible with Intel's new high performance microcomputer systems such as the MCS-88/86<sup>TM</sup>. A frame level command set is achieved by a unique microprogrammed dual processor chip architecture. The processing capability supported by the 8273 relieves the system CPU of the low level real-time tasks normally associated with controllers.

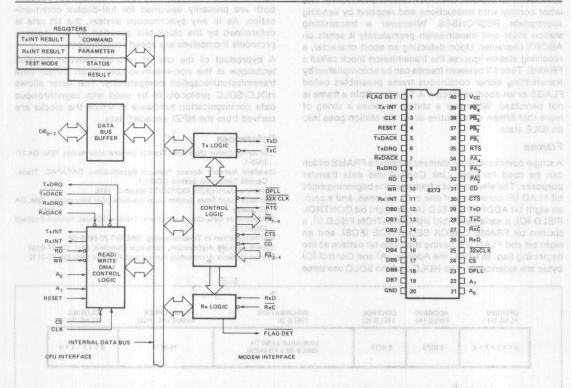

Figure 1. Block Diagram

Figure 2. Pin Configuration

#### A BRIEF DESCRIPTION OF HDLC/SDLC **PROTOCOLS**

#### General

The High Level Data Link Control (HDLC) is a standard communication link protocol established by International Standards Organization (ISO). HDLC is the discipline used to implement ISO X.25 packet switching systems.

The Synchronous Data Link Control (SDLC) is an IBM communication link protocol used to implement the System Network Architecture (SNA). Both the protocols are bit oriented, code independent, and ideal for full duplex communication. Some common applications include terminal to terminal, terminal to CPU, CPU to CPU, satellite communication, packet switching and other high speed data links. In systems which require expensive cabling and interconnect hardware, any of the two protocols could be used to simplify interfacing (by going serial), thereby reducing interconnect hardware costs. Since both the protocols are speed independent, reducing interconnect hardware could become an important application. troller is a dedicated device designed to suppor

#### Network

its it is fully compatible with intel's new high p In both the HDLC and SDLC line protocols, according to a pre-assigned hierarchy, a PRIMARY (Control) STATION controls the overall network (data link) and issues commands to the SECONDARY (Slave) STATIONS. The latter comply with instructions and respond by sending appropriate RESPONSES. Whenever a transmitting station must end transmission prematurely it sends an ABORT character. Upon detecting an abort character, a receiving station ignores the transmission block called a FRAME. Time fill between frames can be accomplished by transmitting either continuous frame preambles called FLAGS or an abort character. A time fill within a frame is not permitted. Whenever a station receives a string of more that fifteen consecutive ones, the station goes into an IDLE state.

A single communication element is called a FRAME which can be used for both Link Control and data transfer purposes. The elements of a frame are the beginning eight bit FLAG (F) consisting of one zero, six ones, and a zero, an eight bit ADDRESS FIELD (A), an eight bit CONTROL FIELD (C), a variable (N-bit) INFORMATION FIELD (I), a sixteen bit FRAME CHECK SEQUENCE (FCS), and an eight bit end FLAG (F), having the same bit pattern as the beginning flag. In HDLC the Address (A) and Control (C) bytes are extendable. The HDLC and the SDLC use three

types of frames; an Information Frame is used to transfer data, a Supervisory Frame is used for control purposes, and a Non-sequenced Frame is used for initialization and control of the secondary stations.

#### Frame Characteristics

An important characteristic of a frame is that its contents are made code transparent by use of a zero bit insertion and deletion technique. Thus, the user can adopt any format or code suitable for his system - it may even be a computer word length or a "memory dump". The frame is bit oriented that is, bits, not characters in each field, have specific meanings. The Frame Check Sequence (FCS) is an error detection scheme similar to the Cyclic Redundancy Checkword (CRC) widely used in magnetic disk storage devices. The Command and Response information frames contain sequence numbers in the control fields identifying the sent and received frames. The sequence numbers are used in Error Recovery Procedures (ERP) and as implicit acknowledgement of frame communication, enhancing the true fullduplex nature of the HDLC/SDLC protocols.

In contrast, BISYNC is basically half-duplex (two way alternate) because of necessity to transmit immediate acknowledgement frames. HDLC/SDLC therefore saves propagation delay times and have a potential of twice the throughput rate of BISYNC.

It is possible to use HDLC or SDLC over half duplex lines but there is a corresponding loss in throughput because both are primarily designed for full-duplex communication. As in any synchronous system, the bit rate is determined by the clock bits supplied by the modem, protocols themselves are speed independent.

A byproduct of the use of zero-bit insertion-deletion technique is the non-return-to-zero invert (NRZI) data transmission/reception compatibility. The latter allows HDLC/SDLC protocols to be used with asynchronous data communication hardware in which the clocks are derived from the NRZI encoded data.

# FUNCTIONAL DESCRIPTION General

The Intel® 8273 HDLC/SDLC controller is a microcomputer peripheral device which supports the International Standards Organization (ISO) High Level Data Link Control (HDLC), and IBM Synchronous Data Link Control (SDLC) communications protocols. This controller minimizes CPU software by supporting a comprehensive frame-level instruction set and by hardware implementation of the low level tasks associated with frame assembly/disassembly and data integrity. The 8273 can be used in either synchronous or asynchronous applications.

In asynchronous applications the data can be programmed to be encoded/decoded in NRZI code. The clock is derived from the NRZI data using a digital phase locked loop. The data transparency is achieved by using a zerobit insertion/deletion technique. The frames are automatically checked for errors during reception by verifying the Frame Check Sequence (FCS); the FCS is automatically generated and appended before the final flag in transmit.

lafrii

The 8273 recognizes and can generate flags (01111110); 4 Abort, Idle, and GA (EOP) characters.

The 8273 can assume either a primary (control) or a secondary (slave) role. It can therefore be readily implemented in an SDLC loop configuration as typified by the IBM 3650 Retail Store System by programming the 8273 into a one-bit delay mode. In such a configuration, a two wire pair can be effectively used for data transfer between controllers and loop stations. The digital phase locked loop output pin can be used by the loop station without the presence of an accurate Tx clock.

**CPU** Interface

The CPU interface is optimized for the MCS-80/85™ bus with an 8257 DMA controller. However, the interface is flexible, and allows either DMA or non-DMA data transfers, interrupt or non-interrupt driven. It further allows maximum line utilization by providing early interrupt mechanism for buffered (only the information field can be transferred to memory) Tx command overlapping. It also provides separate Rx and Tx interrupt output channels for efficient operation. The 8273 keeps the interrupt request active until all the associated interrupt results have been read.

The CPU utilizes the CPU interface to specify commands and transfer data. It consists of seven registers addressed via  $\overline{\text{CS}}$ ,  $A_1$ ,  $A_0$ ,  $\overline{\text{RD}}$  and  $\overline{\text{WR}}$  signals and two independent data registers for receive data and transmit data.  $A_1$ ,  $A_0$  are generally derived from two low order bits of the address bus. If an 8080 based CPU is utilized, the  $\overline{\text{RD}}$  and  $\overline{\text{WR}}$  signals may be driven by the 8228  $\overline{\text{I/OR}}$  and  $\overline{\text{I/OW}}$ . The table shows the seven register select decoding:

#### Register Description

#### Command

Operations are initiated by writing an appropriate command in the Command Register.

#### Parameter and state-search templacetts

Parameters of commands that require additional information are written to this register.

#### Result U90 most stab to brismmed

Contains an immediate result describing an outcome of an executed command.

#### Transmit Interrupt Result

Contains the outcome of 8273 transmit operation (good/bad completion).

#### Receive Interrupt Result

Contains the outcome of 8273 receive operation (good/bad completion), followed by additional results which detail the reason for interrupt.

# Status 101 EXCE of the gromen

The status register reflects the state of the 8273 CPU Interface.

#### **DMA Data Transfers**

The 8273 CPU interface supports two independent data interfaces: receive data and transmit data. At high data transmission speeds the data transfer rate of the 8273 is great enough to justify the use of direct memory access (DMA) for the data transfers. When the 8273 is configured in DMA mode, the elements of the DMA interfaces are:

#### TxDRQ: Transmit DMA Request

Requests a transfer of data between memory and the 8273 for a transmit operation.

#### TxDACK: Transmit DMA Acknowledge

The  $\overline{\text{Tx}}\text{DACK}$  signal notifies the 8273 that a transmit DMA cycle has been granted. It is also used with  $\overline{\text{WR}}$  to transfer data to the 8273 in non-DMA mode. Note:  $\overline{\text{RD}}$  must not be asserted while TxDACK is active.

#### **RxDRQ: Receive DMA Request**

Requests a transfer of data between the 8273 and memory for a receive operation.

#### RxDACK: Receive DMA Acknowledge

The RxDACK signal notifies the 8273 that a receive DMA cycle has been granted. It is also used with RD to read data from the 8273 in non-DMA mode. Note: WR must not be asserted while RxDACK is active.

# RD, WR: Read, Write nio fametxe ent vd gnimit elomas

The RD and WR signals are used to specify the direction of the data transfer.

DMA transfers require the use of a DMA controller such as the Intel 8257. The function of the DMA controller is to provide sequential addresses and timing for the transfer, at a starting address determined by the CPU. Counting of data block lengths is performed by the 8273.

To request a DMA transfer the 8273 raises the appropriate DMA REQUEST. DMA ACKNOWLEDGE and READ enables DMA data onto the bus (independently of CHIP SELECT). DMA ACKNOWLEDGE and WRITE transfers DMA data to the 8273 (independent of CHIP SELECT).

It is also possible to configure the 8273 in the non-DMA data transfer mode. In this mode the CPU module must pass data to the 8273 in response to non-DMA data requests indicated by the status word.

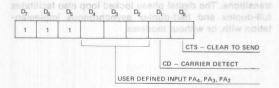

#### Modem Interface

The 8273 Modem interface provides both dedicated and user defined modem control functions. All the control signals are active low so that EIA RS-232C inverting drivers (MC 1488) and inverting receivers (MC 1489) may be used to interface to standard modems. For asynchronous operation, this interface supports programmable NRZI data encode/decode, a digital phase locked loop for efficient clock extraction from NRZI data, and modem control ports with automatic CTS, CD monitoring and RTS generation. This interface also allows the 8273 to operate in PRE-FRAME SYNC mode in which the 8273 prefixes 16 transitions to a frame to synchronize idle lines before transmission of the first flag.

It should be noted that all the 8273 port operations deal—with logical values, for instance, bit D0 of Port A will be a one when CTS (Pin 30) is a physical zero (logical one).

#### Port A - Input Port

During operation, the 8273 interrogates input pins  $\overline{\text{CTS}}$  (Clear to Send) and  $\overline{\text{CD}}$  (Carrier Detect).  $\overline{\text{CTS}}$  is used to condition the start of a transmission. If during transmission  $\overline{\text{CTS}}$  is lost the 8273 generates an interrupt. During reception, if  $\overline{\text{CD}}$  is lost, the 8273 generates an interrupt.

The user defined input bits correspond to the 8273  $PA_4$ ,  $PA_3$  and  $PA_2$  pins. The 8273 does not interrogate or manipulate these bits.

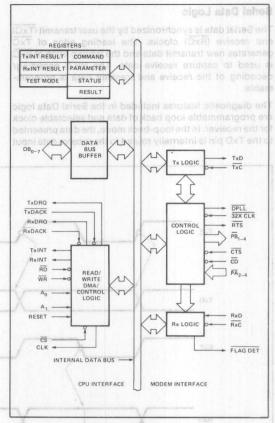

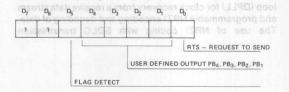

Figure 5. 8273 Block Diagram Showing Control Logic Functions

#### Port B - Output Port

During normal operation, if the CPU sets  $\overline{\text{RTS}}$  active, the 8273 will not change this pin; however, if the CPU sets  $\overline{\text{RTS}}$  inactive, the 8273 will activate it before each transmission and deactivate it one byte time after transmission. While the receiver is active the flag detect pin is pulsed each time a flag sequence is detected in the receive data stream. Following an 8273 reset, all pins of Port B are set to a high, inactive level.

The user defined output bits correspond to the state of PB<sub>4</sub>-PB<sub>1</sub> pins. The 8273 does not interrogate or manipulate these bits.

#### Serial Data Logic

The Serial data is synchronized by the user transmit  $(\overline{TxC})$  and receive  $(\overline{RxC})$  clocks. The leading edge of  $\overline{TxC}$  generates new transmit data and the trailing edge of  $\overline{RxC}$  is used to capture receive data. The NRZI encoding/decoding of the receive and transmit data is programmable.

The diagnostic features included in the Serial Data logic are programmable loop back of data and selectable clock for the receiver. In the loop-back mode, the data presented to the TxD pin is internally routed to the receive data input

circuitry in place of the RxD pin, thus allowing a CPU to send a message to itself to verify operation of the 8273.

In the selectable clock diagnostic feature, when the data is looped back, the receiver may be presented incorrect sample timing by the external circuitry. The user may select to substitute the TxC pin for the RxC input on-chip so that the clock used to generate the loop back data is used to sample it. Since TxD is generated off the leading edge of TxC and RxD is sampled on the trailing edge, the selected clock allows bit synchronism.

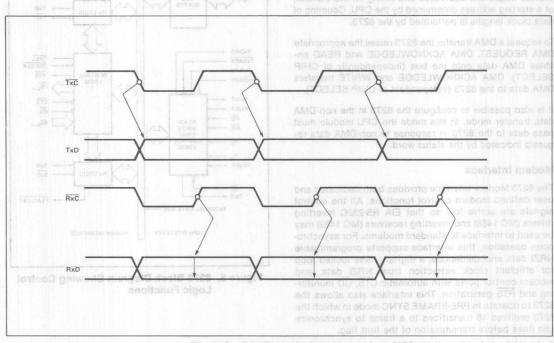

Figure 6. Transmit/Receive Timing on EXSS and its 1840 below ad bloods if

# Asynchronous Mode Interface

Although the 8273 is fully compatible with the HDLC/SDLC communication line protocols, which are primarily designed for synchronous communication, the 8273 can also be used in asynchronous applications by using this interface. The interface employs a digital phase locked loop (DPLL) for clock recovery from a receive data stream and programmable NRZI encoding and decoding of data. The use of NRZI coding with SDLC transmission

guarantees that within a frame, data transitions will occur at least every five bit times — the longest sequence of ones which may be transmitted without zero-bit insertion. The DPLL should be used only when NRZI coding is used since the NRZI coding will transmit zero sequence as line transitions. The digital phase locked loop also facilitates full-duplex and half-duplex asynchronous implementation with, or without modems.

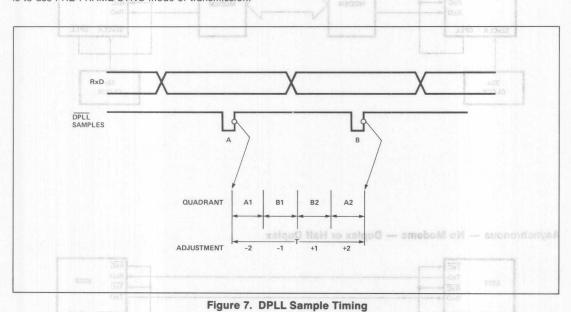

Asynchronous Modems - Duplex or Half Duplex O

#### **Digital Phase Locked Loop**

In asynchronous applications, the clock is derived from the receiver data stream by the use of the digital phase locked loop (DPLL). The DPLL requires a clock input at 32 times the required baud rate. The receive data (RxD) is sampled with this 32X CLK and the 8273 DPLL supplies a sample pulse nominally centered on the RxD bit cells. The DPLL has a built-in "stiffness" which reduces sensitivity to line noise and bit distortion. This is accomplished by making phase error adjustments in discrete increments. Since the nominal pulse is made to occur at 32 counts of the 32X CLK, these counts are subtracted or added to the nominal, depending upon which quadrant of the four error quadrants the data edge occurs in. For example if an RxD edge is detected in quadrant A1, it is apparent that the DPLL sample "A" was placed too close to the trailing edge of the data cell; sample "B" will then be placed at T = (Tnominal - 2 counts) = 30 counts of the 32X CLK to move the sample pulse "B" toward the nominal center of the next bit cell. A data edge occuring in quadrant B1 would cause a smaller adjustment of phase with T = 31 counts of the 32X CLK. Using this technique the DPLL pulse will converge to nominal bit center within 12 data bit times, worst case, with constant incoming RxD edges.

A method of attaining bit synchronism following a line idle is to use PRE-FRAME SYNC mode of transmission.

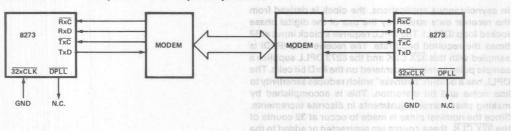

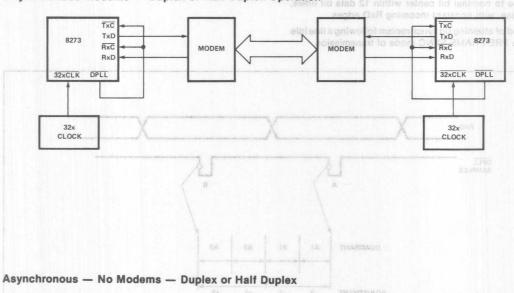

edge is detected in quadrant A1, it is apparent that the

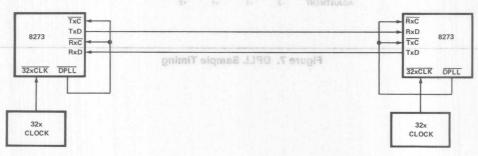

bit celt. A data edge occurring in quadrant B1 would cause

## Synchronous Modem — Duplex or Half Duplex Operation

# Asynchronous Modems — Duplex or Half Duplex Operation us 1190 ent supindosi sidt grisu XIO XSE

#### SDLC Loop

The DPLL simplifies the SDLC loop station implementation. In this application, each secondary station on a loop data link is a repeater set in one-bit delay mode. The signals sent out on the loop by the loop controller (primary station) are relayed from station to station then, back to the controller. Any secondary station finding its address in the A field captures the frame for action at that station. All received frames are relayed to the next station on the loop.

Loop stations are required to derive bit timing from the incoming NRZI data stream. The DPLL generates sample Rx clock timing for reception and uses the same clock to implement Tx clock timing.

The 8273 is an intelligent peripheral controller which relieves the CPU of many of the role tasks associated with relieves the CPU of many of the role tasks associated with constructing and receiving frames. It is fully compatible at a cospts commands from a CPU, executes these commands and provides an interrupt and Result back to be CPU at the end of the execution. The communication with the CPU is done by activation of CS, RD, WR pins, while the An Ao select the appropriate registers on the thip as described in the Hardware Description Section.

The 8273 operation is composed of the following

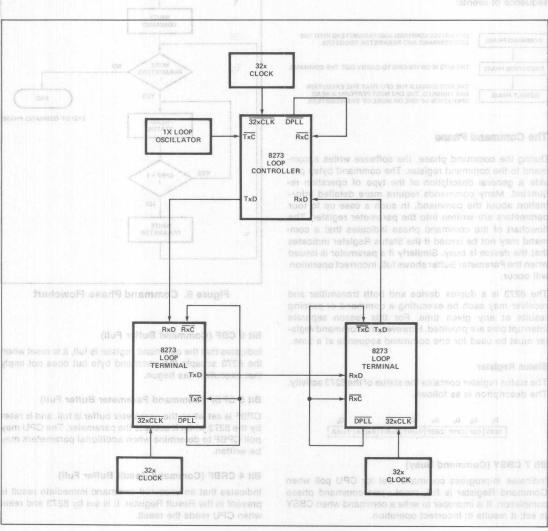

Figure 8. SDLC Loop Application

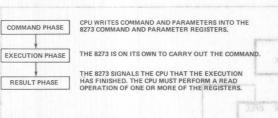

#### PRINCIPLES OF OPERATION

The 8273 is an intelligent peripheral controller which relieves the CPU of many of the rote tasks associated with constructing and receiving frames. It is fully compatible with the MCS-80/85™ system bus. As a peripheral device, it accepts commands from a CPU, executes these commands and provides an Interrupt and Result back to the CPU at the end of the execution. The communication with the CPU is done by activation of CS, RD, WR pins, while the A₁, A₀ select the appropriate registers on the chip as described in the Hardware Description Section.

The 8273 operation is composed of the following sequence of events:

#### The Command Phase

During the command phase, the software writes a command to the command register. The command bytes provide a general description of the type of operation requested. Many commands require more detailed information about the command. In such a case up to four parameters are written into the parameter register. The flowchart of the command phase indicates that a command may not be issued if the Status Register indicates that the device is busy. Similarly if a parameter is issued when the Parameter Buffer shows full, incorrect operation will occur.

The 8273 is a duplex device and both transmitter and receiver may each be executing a command or passing results at any given time. For this reason separate interrupt pins are provided. However, the command register must be used for one command sequence at a time.

#### Status Register

The status register contains the status of the 8273 activity. The description is as follows.

#### Bit 7 CBSY (Command Busy)

Indicates in-progress command, set for CPU poll when Command Register is full, reset upon command phase completion. It is improper to write a command when CBSY is set; it results in incorrect operation.

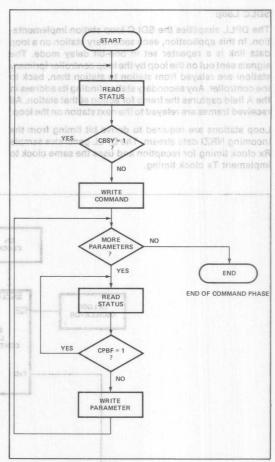

Figure 9. Command Phase Flowchart

#### Bit 6 CBF (Command Buffer Full)

Indicates that the command register is full, it is reset when the 8273 accepts the command byte but does not imply that execution has begun.

#### Bit 5 CPBF (Command Parameter Buffer Full)

CPBF is set when the parameter buffer is full, and is reset by the 8273 when it accepts the parameter. The CPU may poll CPBF to determine when additional parameters may be written.

#### Bit 4 CRBF (Command Result Buffer Full)

Indicates that an executed command immediate result is present in the Result Register. It is set by 8273 and reset when CPU reads the result.

Figure 8. SDLC Loop Application

1-200

#### Bit 3 RxINT (Receiver Interrupt) and and not not hope of

RXINT indicates that the receiver requires CPU attention. It is identical to RXINT (pin 11) and is set by the 8273 either upon good/bad completion of a specified command or by Non-DMA data transfer. It is reset only after the CPU has read the result byte or has received a data byte from the 8273 in a Non-DMA data transfer.

#### Bit 2 TxINT (Transmitter Interrupt)

The TxINT indicates that the transmitter requires CPU attention. It is identical to TxINT (pin 2). It is set by 8273 either upon good/bad completion of a specified command or by Non-DMA data transfer. It is reset only after the CPU has read the result byte or has transferred transmit data byte to the 8273 in a Non-DMA transfer.

#### Bit 1 RxIRA (Receiver Interrupt Result Available)

The RxIRA is set by the 8273 when an interrupt result byte is placed in the RxINT register. It is reset after the CPU has read the RxINT register.

#### Bit 0 TxIRA (Transmitter Interrupt Result Available)

The TxIRA is set by the 8273 when an interrupt result byte is placed in the TxINT register. It is reset when the CPU has read the TxINT register.

# Immediate result is provided by seed Port B which have such as Read Port A and Read Port B which have

Upon accepting the last parameter, the 8273 enters into the Execution Phase. The execution phase may consist of a DMA or other activity, and may or may not require CPU intervention. The CPU intervention is eliminated in this phase if the system utilizes DMA for the data transfers, otherwise, for non-DMA data transfers, the CPU is interrupted by the 8273 via TxINT and RxINT pins, for each data byte request.

#### The Result Phase

During the result phase, the 8273 notifies the CPU of the execution outcome of a command. This phase is initiated by:

TxI/R or 8x Interrupt Result Register RxI/R. The result

- 1. The successful completion of an operation
- 2. An error detected during an operation.

To facilitate quick network software decisions, two types of execution results are provided:

- 1. An Immediate Result
- 2. A Non-Immediate Result

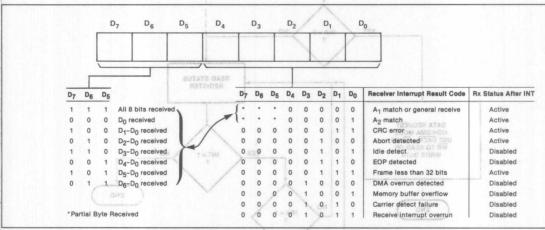

Figure 10. Rx Interrupt Result Byte Format

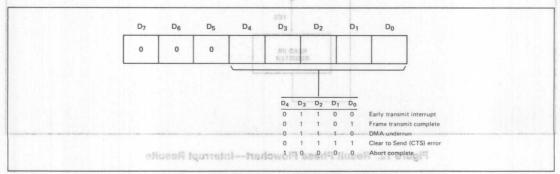

Figure 11. Tx Interrupt Result Byte Format

lami

Immediate result is provided by the 8273 for commands such as Read Port A and Read Port B which have information (CTS, CD, RTS, etc.) that the network software needs to make quick operational decisions.

A command which cannot provide an immediate result will generate an interrupt to signal the beginning of the Result phase. The immediate results are provided in the Result Register; all non-immediate results are available upon device interrupt, through Tx Interrupt Result Register TxI/R or Rx Interrupt Result Register RxI/R. The result may consist of a one-byte interrupt code indicating the

condition for the interrupt and, if required, one or more bytes which detail the condition.

#### Tx and Rx Interrupt Result Registers

The Result Registers have a result code, the three high order bits  $D_7 - D_5$  of which are set to zero for all but the receive command. This command result contains a count that indicates the number of bits received in the last byte. If a partial byte is received, the high order bits of the last data byte are indeterminate.

All results indicated in the command summary must be read during the result phase along about 40 control of the command summary must be

#### General

The 8273 HDLC/SDLC controller supports a comprehensive set of high level commands which allows the 8273 to be readily used in full-duplex, half-duplex, synchronous, asynchronous and SDLC loop configuration, with or without modems. These frame-level commands minimize CPU and software overhead. The 8273 has address and control byte buffers which allow the receive and transmit commands to be used in buffered or non-buffered modes.

In buffered transmit mode, the 8273 transmits a flag automatically, reads the Address and Control buffer registers and transmits the fields, then via DMA, it fetches the information field. The 8273, having transmitted the information field, automatically appends the Frame Check Sequence (FCS) and the end flag. Correspondingly, in buffered read mode, the Address and Control fields are stored in their respective buffer registers and only Information Field is transferred to memory.

In non-buffered transmit mode, the 8273 transmits the beginning flag automatically, then fetches and transmits the Address, Control and Information fields from the memory, appends the FCS character and an end flag. In the non-buffered receive mode the entire contents of a frame are sent to memory with the exception of the flags and FCS.

#### **HDLC** Implementation

HDLC Address and Control field are extendable. The extension is selected by setting the low order bit of the field to be extended to a one, a zero in the low order bit indicates the last byte of the respective field.

Since Address/Control field extension is normally done with software to maximize extension flexibility, the 8273 does not create or operate upon contents of the extended HDLC Address/Control fields. Extended fields are transparently passed by the 8273 to user as either interrupt results or data transfer requests. Software must assemble the fields for transmission and interrogate them upon reception.

However, the user can take advantage of the powerful 8273 commands to minimize CPU/Software overhead and simplify buffer management in handling extended fields. For instance buffered mode can be used to separate the first two bytes, then interrogate the others from buffer. Buffered mode is perfect for a two byte address field.

The 8273 when programmed, recognizes protocol characters unique to HDLC such as Abort, which is a string of seven or more ones (011111111). Since Abort character is the same as the GA (EOP) character used in SDLC Loop applications, Loop Transmit and Receive commands are not recommended to be used in HDLC. HDLC does not support Loop mode.

#### **Initialization Set/Reset Commands**

These commands are used to manipulate data within the 8273 registers. The Set commands have a single parameter which is a mask that corresponds to the bits to be set. (They perform a logical-OR of the specified register with the mask provided as a parameter). The Register commands have a single parameter which is a mask that has a zero in the bit positions that are to be reset. (They perform a logical-AND of the specified register with the mask).

#### Set One-Bit Delay (CMD Code A4)

	A <sub>1</sub>	A <sub>0</sub>	D <sub>7</sub>	$D_6$	D <sub>5</sub>	$D_4$	$D_3$	D <sub>2</sub>	D <sub>1</sub>	Do
CMD:										
PAR:	0	1	1	0	0	0	0	0	0	0

When one bit delay is set, 8273 retransmits the received data stream one bit delayed. This mode is entered at a receiver character boundary, and should only be used by Loop Stations.

#### Reset One-Bit Delay (CMD Code 64)

	A <sub>1</sub>	A <sub>0</sub>	D <sub>7</sub>	$D_6$	05	$D_4$	$D_3$	$D_2$	D	$D_0$
CMD:										
PAR:	0	1	0	1	1	1	1	1	1	1

The 8273 stops the one bit delayed retransmission mode.

#### Set Data Transfer Mode (CMD Code 97)

		Ao								
CMD:	0	0	1	0	0	1	0	1	1	1
PAR:	0	1	0	0	0	0	0	0	0	1

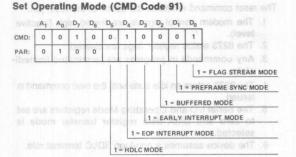

When the data transfer mode is set, the 8273 will interrupt when data bytes are required for transmission or are available from a receive. If a transmit interrupt occurs and the status indicates that there is no Transmit Result (TxIRA = 0), the interrupt is a transmit data request. If a receive interrupt occurs and the status indicates that there is no receive result (RxIRA = 0), the interrupt is a receive data request.

#### Reset Data Transfer Mode (CMD Code 57)

	A <sub>1</sub>	A <sub>0</sub>	D <sub>7</sub>	D <sub>6</sub>	$D_5$	$D_4$	$D_3$	$D_2$	D <sub>1</sub>	Do
CMD:	0	0	0	1	0	1	0	1	1	1
PAR:	0	1	1	1	1	1	1	1	1	0

If the Data Transfer Mode is reset, the 8273 data transfers are performed through the DMA requests without interrupting the CPU.

#### Reset Operating Mode (CMD Code 51)

	A <sub>1</sub>	Ao	D <sub>7</sub>	D <sub>6</sub>	D <sub>5</sub>	D <sub>4</sub>	D <sub>3</sub>	D2	D <sub>1</sub>	Do
CMD:	0	0	0	1	0	1	0	0	0	61/1
PAR:	0	1	1	1		cincen.	UNIV.	-		

Any mode switches set in CMD code 91 can be reset using this command by placing zeros in the appropriate positions.

#### (D5) HDLC Mode

In HDLC mode, a bit sequence of seven ones (01111111) is interpreted as an abort character. Otherwise, eight ones (011111111) signal an abort.

#### (D4) EOP Interrupt Mode

In EOP interrupt mode, an interrupt is generated whenever an EOP character (01111111) is detected by an active receiver. This mode is useful for the implementation of an SDLC loop controller in detecting the end of a message stream after a loop poll.

#### (D3) Transmitter Early Interrupt Mode (Tx)

The early interrupt mode is specified to indicate when the 8273 should generate an end of frame interrupt. When set, an early interrupt is generated when the last data character has been passed to the 8273. If the user software responds with another transmit command before the final flag is sent, the final flag interrupt will not be generated and a new frame will immediately begin when the current frame is complete. This permits frames to be separated by a single flag. If no additional Tx commands are provided, a final interrupt will follow.

Note: In buffered mode, if a supervisory frame (no Information) Transmit command is sent in response to an early Transmit Interrupt, the 8273 will repeatedly transmit the same supervisory frame with one flag in between, until a non-supervisory transmit is issued.

Early transmitter interrupt can be used in buffered mode by waiting for a transmit complete interrupt instead of early Transmit Interrupt before issuing a transmit frame command for a supervisory frame. See Figure 14.

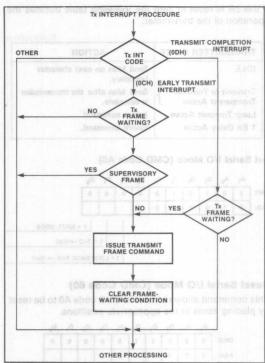

Figure 14.

If this bit is zero, the interrupt will be generated only after the final flag has been transmitted.

#### (D2) Buffered Mode

If the buffered mode bit is set to a one, the first two bytes (normally the address (A) and control (C) fields) of a frame are buffered by the 8273. If this bit is a zero the address and control fields are passed to and from memory.

#### (D1) Preframe Sync Mode

If this bit is set to a one the 8273 will transmit two characters before the first flag of a frame.

To guarantee sixteen line transitions, the 8273 sends two bytes of data  $(00)_{\rm H}$  if NRZI is set or data  $(55)_{\rm H}$  if NRZI is not set.

#### (D0) Flag Stream Mode 2-YSAD men book MSI of neteR

If this bit is set to a one, the following table outlines the operation of the transmitter.

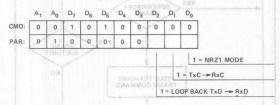

TRANSMITTER STATE	ACTION
Idle o o o o	Send Flags immediately.
Transmit or Transmit-	Send Flags after the
Transparent Active	transmission complete
Loop Transmit Active	Ignore command.
1 Bit Delay Active	Ignore command.

If this bit is reset to zero the following table outlines the operation of the transmitter.

TRANSMITTER STATE	THE ACTION HEHT
IDLE	Send Idles on next character boundary.
Transmit or Transmit-Transparent Active	Send Idles after the transmission is complete.
Loop Transmit Active	Ignore command.
1 Bit Delay Active	Ignore command.

#### Set Serial I/O Mode (CMD Code A0)

#### Reset Serial I/O Mode (CMD Code 60)

This command allows bits set in CMD code A0 to be reset by placing zeros in the appropriate positions.

	Α1	A <sub>0</sub>	D <sub>7</sub>	D <sub>6</sub>	D <sub>5</sub>	D <sub>4</sub>	D <sub>3</sub>	D <sub>2</sub>	D <sub>1</sub>	D <sub>0</sub>
CMD:	0	0	0	1	1	0	0	0	0	0
PAR:	0	1	18	413	10108	9.18	110			

#### (D2) Loop Back

If this bit is set to a one, the transmit data is internally routed to the receive data circuitry.

(D2) Buffered Mode

Figure 14,

#### (D1) TxC → RxC

If this bit is set to a one, the transmit clock is internally routed to the receive clock circuitry. It is normally used with the loop back bit (D2). and bessed our abject fortings

#### (D0) NRZI Mode

If this bit is set to a one, NRZI encoding and decoding of transmit and receive data is provided. If this bit is a zero, the transmit and receive data is treated as a normal positive logic

NRZI encoding specifies that a zero causes a change in the polarity of the transmitted signal and a one causes no polarity change. NRZI is used in all asynchronous operations. Refer to IBM document GA27-3093 for details.

#### **Reset Device Command**

	A <sub>1</sub>	A <sub>0</sub>	D <sub>7</sub>	D <sub>6</sub>	D <sub>5</sub>	D <sub>4</sub>	D <sub>3</sub>	D <sub>2</sub>	D <sub>1</sub>	D <sub>0</sub>	
TMR:	1	0	0	0	0	0	0	0	0	121	A.F
TMR:	dig8	0	0	0	0	0	0	0	0	0	Si

An 8273 reset command is executed by outputing a (01)<sub>H</sub> followed by (00)<sub>H</sub> to the reset register (TMR). See 8273 AC timing characteristics for Reset pulse specifications.

The reset command emulates the action of the reset pin.

- 1. The modem control signals are forced high (inactive
- 2. The 8273 status register flags are cleared.
- 3. Any commands in progress are terminated immedi-
- 4. The 8273 enters an idle state until the next command is issued
- 5. The Serial I/O and Operating Mode registers are set to zero and DMA data register transfer mode is selected. agom тарияя атиг чо
- 6. The device assumes a non-loop SDLC terminal role.

#### Receive Commandshoo (IMO) show gallanego leasest

The 8273 supports three receive commands: General Receive, Selective Receive, and Selective Loop Receive.

#### General Receive (CMD Code C0)

General receive is a receive mode in which frames are received regardless of the contents of the address field.

	A <sub>1</sub>	A <sub>0</sub>	D <sub>7</sub>	D <sub>6</sub>	D <sub>5</sub>	D <sub>4</sub>	$D_3$	$D_2$	D <sub>1</sub>	D <sub>0</sub>			
CMD:	0	0	1	1	0	0	0	0	0	0			
PAR:	0	1		LEAST SIGNIFICANT BYTE OF THE RECEIVE BUFFER LENGTH (B0)									
PAR:	0	111		OST SIGNIFICANT BYTE OF RECEIVE									

#### NOTES:

- 1. If buffered mode is specified, the R0, R1 receive frame length (result) is the number of data bytes received.
- 2. If non-buffered mode is specified, the R0, R1 receive frame length (result) is the number of data bytes received plus two (the count includes the address and control bytes).
- 3. The frame check sequence (FCS) is not transferred to memory.
- Frames with less than 32 bits between flags are ignored (no interrupt generated) if the buffered mode is specified.
- 5. In the non-buffered mode an interrupt is generated when a less than 32 bit frame is received, since data transfer requests have occurred.
- 6. The 8273 receiver is always disabled when an Idle is received after a valid frame. The CPU module must issue a receive command to re-enable the receiver.
- The intervening ABORT character between a final flag and an IDLE does not generate an interrupt.
- 8. If an ABORT Character is not preceded by a flag and is followed by an IDLE, an interrupt will be generated for the ABORT followed by an IDLE interrupt one character time later. The reception of an ABORT will disable the receiver.

#### Selective Receive (CMD Code C1) com benefited at selection

	A1.	Ao	D <sub>7</sub>	D <sub>6</sub>	D <sub>5</sub>	D <sub>4</sub>	D <sub>3</sub>	D <sub>2</sub>	D <sub>1</sub>	D <sub>0</sub>				
CMD:	0	0	1	1.	0	0	0	0	0	1				
PAR:	0	1		LEAST SIGNIFICANT BYTE OF THE RECEIVE BUFFER LENGTH (B0)										
PAR:	0	1		MOST SIGNIFICANT BYTE OF RECEIVE BUFFER LENGTH (B1)										
PAR:	0	o to			E FR	AME A1)	ADDI	RESS	MAT	СН				
PAR:	0	115	40.	RECEIVE FRAME ADDRESS MATCH										

Selective receive is a receive mode in which frames are ignored unless the address field matches any one of two address fields given to the 8273 as parameters.

When selective receive is used in HDLC the 8273 looks at the first character, if extended, software must then decide if the message is for this unit.

## Selective Loop Receive (CMD Code C2)

	A <sub>1</sub>	$A_0$	D <sub>7</sub>	D <sub>6</sub>	D <sub>5</sub>	D <sub>4</sub>	D <sub>3</sub>	D <sub>2</sub>	D <sub>1</sub>	D <sub>0</sub>	1091	
CMD:	0	0	1	1	0	0	0	0	1	0	]	
PAR:	0	0					NT B			HE	11100	
PAR:	0	1			GNIF			TE O	FRE	CEIVE	10	
PAR:	0	1			E FR		ADDI	RESS	MAT	СН	0	
PAR:	0	11			E FR		ADDI	RESS	MAT	СН		

Selective loop receive operates like selective receive except that the transmitter is placed in flag stream mode automatically after detecting an EOP (01111111) following a valid received frame. The one bit delay mode is also reset at the end of a selective loop receive.

#### Receive Disable (CMD Code C5)

Terminates an active receive command immediately.

	A <sub>1</sub>	A <sub>0</sub>	D <sub>7</sub>	D <sub>6</sub>	$D_5$	D <sub>4</sub>	D <sub>3</sub>	$D_2$	D <sub>1</sub>	D <sub>0</sub>
CMD:	0.	0	1	1	0	0	0.	1	0	1

#### **Transmit Commands**

The 8273 supports three transmit commands: Transmit Frame, Loop Transmit, Transmit Transparent.

#### Transmit Frame (CMD Code C8)

	A <sub>1</sub>	A <sub>0</sub>	D <sub>7</sub>	D <sub>6</sub>	D <sub>5</sub>	D <sub>4</sub>	D <sub>3</sub>	D <sub>2</sub>	D <sub>1</sub>	D <sub>0</sub>	
CMD:	0	0	1	1	0	0	1	0	0	0	
PAR:	0	1			IGNI			YTE	OF	ALTR	on
PAR:	0	Y 1			GNIF			TE O	F <sub>(O,</sub>	A1,(A	0FI
PAR:	0	1	AD	DRES	S FIE	LD (	OF TE	RANS	MIT F	RAME	(A)
PAR:	0	1	COI	VTRO	L FI	ELD (	OF TE	RANS	MIT	FRAME	(C)

Transmits one frame including; initial flag, frame check sequence, and the final flag.

If the buffered mode is specified, the L0, L1, frame length provided as a parameter is the length of the information field and the address and control fields must be input.

In unbuffered mode the frame length provided must be the length of the information field plus two and the address and control fields must be the first two bytes of data. Thus only the frame length bytes are required as parameters.

#### Loop Transmit (CMD Code CA)

	A <sub>1</sub>	A <sub>0</sub>	D <sub>7</sub>	D <sub>6</sub>	D <sub>5</sub>	D <sub>4</sub>	$D_3$	$D_2$	D <sub>1</sub>	D <sub>0</sub>			
CMD:	0	0	1	1	0	0	1	0	1	0			
PAR:	0	0.8				FICA TH (		YTE	OF	or und it Sat P			
PAR:	0	1		MOST SIGNIFICANT BYTE OF FRAME LENGTH (L1)									
PAR:	0	1	ADI	ORES	S FIE	LD O	FTR	ANS	/IT F	RAME (A)			
PAR:	0	1	CON	ITRO	L FIE	LDC	FTR	ANS	MITF	RAME (C)			

Transmits one frame in the same manner as the transmit frame command except:

- If the flag stream mode is not active transmission will begin after a received EOP has been converted to a flag.

  (SS abo C CMC) B not bear?
- If the flag stream mode is active transmission will begin at the next flag boundary for buffered mode or at the third flag boundary for non-buffered mode.
- At the end of a loop transmit the one-bit delay mode is entered and the flag stream mode is reset.

#### Transmit Transparent (CMD Coded C9)

	A <sub>1</sub>	A <sub>0</sub>	D <sub>7</sub>	D <sub>6</sub>	D <sub>5</sub>	D <sub>4</sub>	D <sub>3</sub>	D <sub>2</sub>	D <sub>1</sub>	D <sub>0</sub>
CMD:	0	0	.1	1	0	0	1	0	0	1
PAR:	0	1		AST S				YTE (	OF	
PAR:	0 .	1		ST SI				TE O	F	

The 8273 will transmit a block of raw data without protocol, i.e., no zero bit insertion, flags, or frame check sequences.

SEPE Command Summers

#### **Abort Transmit Commands**

An abort command is supported for each type of transmit command. The abort commands are ignored if a transmit command is not in progress.

#### Abort Transmit Frame (CMD Code CC)

		A <sub>0</sub>								
CMD:	0	0	. 1	1	0	0	.1	1	0	0

After an abort character (eight contiguous ones) is transmitted, the transmitter reverts to sending flags or idles as a function of the flag stream mode specified.

#### Abort Loop Transmit (CMD Code CE)

		A <sub>1</sub>	A <sub>0</sub>	D <sub>7</sub>	D <sub>6</sub>	D <sub>5</sub>	D <sub>4</sub>	$D_3$	D <sub>2</sub>	D <sub>1</sub>	D <sub>0</sub>	
L0,L1,(A,C)	CMD:	0	0	1	1	0	0	1	18	1	0	
LOLITIALCY	PAR:	NON	IE	1		7	15		tim	ans	TO	

After a flag is transmitted the transmitter reverts to one bit delay mode.

#### Abort Transmit Transparent (CMD Code CD)

						D <sub>4</sub>				
CMD:	0	0	. 1	1	0	. 0	1	1	0	1

The transmitter reverts to sending flags or idles as a function of the flag stream mode specified.

#### **Modem Control Commands**

The modem control commands are used to manipulate the modem control ports.

When read Port A or Port B commands are executed the result of the command is returned in the result register. The Bit Set Port B command requires a parameter that is a mask that corresponds to the bits to be set. The Bit Reset Port B command requires a mask that has a zero in the bit positions that are to be reset.

#### Read Port A (CMD Code 22)

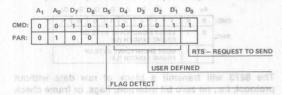

#### Read Port B (CMD Code 23)

#### Set Port B Bits (CMD Code A3)

This command allows user defined Port B pins to be set.

#### (D5) Flag Detect

This bit can be used to set the flag detect pin. However, it will be reset when the next flag is detected.

### (D4-D1) User Defined Outputs of risvip abidit assubbs

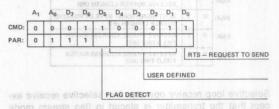

These bits correspond to the state of the PB<sub>4</sub>-PB<sub>1</sub> output pins.

#### (Do) Request to Send

This is a dedicated 8273 modem control signal, and reflects the same logical state of RTS pin.

#### Reset Port B Bits (CMD Code 63)

This command allows Port B user defined bits to be reset.

This command allows Port B (D<sub>4</sub>-D<sub>1</sub>) user defined bits to be reset. These bits correspond to Output Port pins (PB<sub>4</sub>-PB<sub>1</sub>).

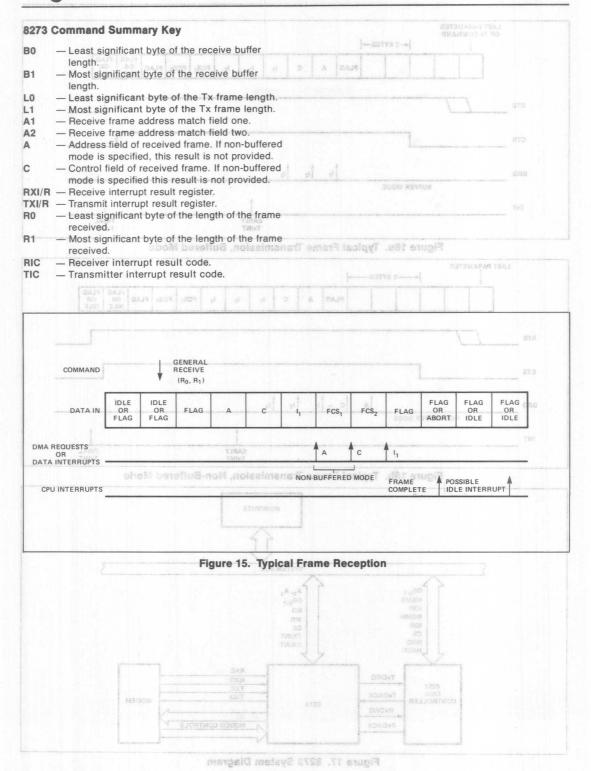

#### 8273 Command Summary

  - Automatic Zero Bit Insertion and Deletion
  - Automatic CRC Generation and Checking (CCITT-16)
  - CCITT X.25 Compatible

The Intel® 8274 Multi-Protocol Series Controller (MPSC) is designed to interface High Speed Communications Lines using Asynchronous, IBM Bisync, and SDLC/HDLC protocol to Intel microcomputer systems. It can be interfaced with Intel's MCS-48, -85, -51; iAPX-86, and -88 families, the 8237 DMA Controller, or the 8089 I/O Processor in polled, interrupt driven, or DMA driven modes of operation.

The MPSC is a 40 pin device fabricated using Intel's High Performance HMOS Technology.

GENI	FRAI	DESCR	IDTION

The Intel® 8274 Multi-Protocol Serial Controller is a microcomputer peripheral device which supports Asynchronous (Start/Stop), Byte Synchronous (Monosync, IBM Bisync), and Bit Synchronous (ISO's HDLC, IBM's SDLC) protocols. This controller's flexible architecture allows easy implementation of many variations of these three protocols with low software and hardware overhead.

The Multi-Protocol Serial Controller (MPSC) implements two independent serial receiver/transmitter channels.

The MPSC supports several microprocessor interface options; Polled, Wait, Interrupt driven and DMA driven. The MPSC is designed to support Intel's® MCS-85 and iAPX 86, 88 families.

This data sheet will describe the serial protocol functions, the microprocessor interface, a detailed register and command description, general system operations, specifications, and waveforms.

#### **FUNCTIONAL DESCRIPTION**

This section of the data sheet describes how the Asynchronous and Synchronous protocols are implemented in the MPSC. It describes general considerations, transmit operation, and receive operation for Asynchronous, Byte Synchronous, and Bit Synchronous protocols.

#### **ASYNCHRONOUS OPERATIONS**

Receive Data (Chounel B): This line

# General beau et riq ant ris

For operation in the asynchronous mode, the MPSC must be initialized with the following information: character length (WR3; D7, D6 and WR5; D6, D5), clock rate (WR4; D7, D6), number of stop bits (WR4; D3, D2), odd, even or no parity (WR4; D1, D0), interrupt mode (WR1, WR2), and receiver (WR3; D0) or transmitter (WR5; D3) enable. When loading these parameters into the MPSC, WR4 information must

be written before the WR1, WR3, WR5 parameters/ commands. (See Detailed Command Description Section).

For transmission via a modem or RS232C interface, the Request To Send (RTS) (WR5; D1) and Data Terminal Ready (DTR) (WR5; D7) bits must be set along with the Transmit Enable bit (WR5; D3). Setting the Auto Enables (WR3; D5) bit allows the programmer to send the first character of the message without waiting for a clear to send (CTS).

Both the Framing Error and Receive Overrun Error flags are latched and cause an interrupt, i.e., if status affects vector (WR1B; D2) is selected, the interrupt vector indicates a special Receive condition.

If the External/Status Interrupt bit (WR1; D0) is enabled, Break Detect (RR0; D7) and Carrier Detect (RR0; D3) will cause an interrupt. Reset External/Status Interrupts (WR0; D5, D4, D3) will clear Break Detect and Carrier Detect bits if they are set.

A status read after a data read will include error status for the next word in the buffer. If the Interrupt on First Character (WR1; D4, D3) is selected, then data and error status are held until an Error Reset command (WR0; D5, D4, D3) is given.

If the Interrupt on Every Character Mode bit (WR1; D4, D3) is selected, the interrupt vector is different if there is an error status in RR1. When the character is read, the error status bit is set and the Special Receive Condition vector is returned if Status Affects vector (WR1B; D2) is selected.

In a polled environment, the Receive Character Available bit (RR0; D0) must be monitored so that the CPU can determine when data is available. The bit is reset automatically when the data is read. If the X1 clock mode is selected, the bit synchronization must be accomplished externally.

#### **Transmit**

The transmit function begins when the Transmit Enable bit (WR5; D3) is set. The MPSC automatically adds the start bit, the programmed parity bit (odd, even or no parity) and the programmed number of stop bits (1, 1.5 or 2 bits) to the data character being transmitted.

The Serial data is shifted out from the Transmit Data (TxD) output on the falling edge of the Transmit Clock (TxC) input, at a rate programmable to 1, 1/16, 1/32nd, or 1/64th of the clock rate supplied to the TxC input.

The TxD output is held high when the transmitter has no data to send, unless, under program control, the Send Break (WR5; D4) command is issued to hold the TxD low.

If the External/STATUS Interrupt bit (WR1; D0) is set, the status of CD, CTS and SYNDET are monitored, and, if any changes occur for a period of time greater than the minimum specified pulse width, an interrupt is generated. CTS is usually monitored using this interrupt feature.

If the Auto Enables (WR; D5) option is selected the programmer need not wait for the CTS before sending the first character. The MPSC will automatically wait for the CTS pin to go active before the transmission begins.

The Transmit Buffer Empty bit (RR0; D2) is set by the MPSC when the data byte from the buffer is loaded in the transmit shift register. The data is written to the MPSC only when the Tx buffer becomes empty to prevent overwriting.

WR5	DTR		7 b/char	SEND	Tx	0	RTS	0	
			6 b/char 8 b/char	BREAK	ENABLE				

#### Receive

The receive function begins when the Receive Enable (WR3; D0) bit is set. If the Auto Enables (WR3; D5) option is selected, then Carrier Detect (CD) must also be low. A valid start bit is detected if a low persists for at least 1/2 bit time on the Receive Data (RxD) input.

If the X1 clock mode is selected, the bit sy

tion must be accomplished externally

The data is sampled at mid-bit time, on the rising edge of RxC, until the entire character is assembled. The receiver inserts 1's when a character is less than 8 bits. If parity (WR4; D1, D0) is enabled and the character is less than 8 bits the parity bit is not stripped from the character.

The receiver also stores error status for each of the 3 data characters in the data buffer. When a parity error is detected, the parity error flag (RR1; D4) is set and remains set until it is reset by the Error Reset command (WR0; D5, D4, D3).

When a character is assembled without a stop bit being detected, the Framing Error bit (RR1; D6) is set. The detection of a Framing Error adds an additional 1/2 bit time to the character time so the Framing Error is not interpreted as a new start bit.

If the CPU fails to read a data character while more than three characters have been received, the Receive Overrun bit (RR1; D5) is set. Only the overwritten character is flagged with the Receive Overrun bit. When this occurs, the fourth character assembled replaces the third character in the receive buffers. The Receive Overrun bit (RR1; D5) is reset by the Error Reset command (WR0; D5, D4, D3).

# SYNCHRONOUS OPERATION— MONO SYNC, BI SYNC

#### General necession via a modern or Research For

The MPSC must be initialized with the following parameters: odd or even parity (WR4; D1,D0), X1 clock mode (WR4; D7, D6), 8- or 16-bit sync character (WR4; D5, D4), CRC polynomial (WR5; D2), Transmitter Enable (WR5; D3), interrupt modes (WR1, WR2), transmit character length (WR5; D6, D5) and receive character length (WR3; D7, D6). WR4 parameters must be written before WR1, WR3, WR5, WR6 and WR7.

The data is transmitted on the falling edge of the Transmit Clock, (TxC) and is received on the rising edge of Receive Clock (RxC). The X1 clock is used for both transmit and receive operations for all three sync modes: Mono, Bi and External.

#### Transmit Set-Up-Monosync, Bisync at A

Transmit data is held high after channel reset, or if the transmitter is not enabled. A break may be programmed to generate a spacing line that begins as soon as the Send Break (WR5; D4) bit is set. With the transmitter fully initialized and enabled, the default condition is continuous transmission of the 8- or 16-bit sync character.

Using interrupts for data transfer requires that the Transmit Interupt/DMA Enable bit (WR1; D1) be set. An interrupt is generated each time the transmit buffer becomes empty. The interrupt can be satisfied

either by writing another character into the transmitter or by resetting the Transmitter Interrupt/DMA Pending latch with a Reset Transmitter Interrupt/DMA Pending Command (WR0; D5, D4, D3). If nothing more is written into the transmitter, there can be no further Transmit Buffer Empty interrupt, but this situation does cause a Transmit Underrun condition (RR0; D6).

Data Transfers using the RDY signal are for software controlled data transfers such as block moves. RDY tells the CPU that the MPSC is not ready to accept/provide data and that the CPU must extend the output/input cycle. DMA data transfers use the TxDRQ A/B signals which indicate that the transmit buffer is empty, and that the MPSC is ready to accept the next data character. If the data character is not loaded into the MPSC by the time the transmit shift register is empty, the MPSC enters the Transmit Underrun condition.

The MPSC has two programmable options for solving the transmit underrun condition: it can insert sync characters, or it can send the CRC characters generated so far, followed by sync characters. Following a chip or channel reset, the Transmit Underrun/EOM status bit (RR0; D6) is in a set condition allowing the insertion of sync characters when there is no data to send. The CRC is not calculated on these automatically inserted sync characters. When the CPU detects the end of message, a Reset Transmit Underrun/EOM command can be issued. This allows CRC to be sent when the transmitter has no data to send.

In the case of sync insertion, an interrupt is generated only after the first automatically inserted sync character has been loaded in Transmit Shift Register. The status indicates the Transmit Underrun/EOM bit and the Transmit Buffer Empty bit are set.

In the case of CRC insertion, the Transmit Underrun/EOM bit is set and the Transmit Buffer Empty bit is reset while CRC is being sent. When CRC has been completely sent, the Transmit Buffer Empty status bit is set and an interrupt is generated to indicate to the CPU that another message can begin (this interrupt occurs because CRC has been sent and sync has been loaded into the Tx Shift Register). If no more messages are to be sent, the program can terminate transmission by resetting RTS, and disabiling the transmitter (WR5; D3).

Bisync CRC Generation. Setting the Transmit CRC enable bit (WR5; D0) indicates CRC accumulation when the program sends the first data character to

the MPSC. Although the MPSC automatically transmits up to two sync characters (16 bit sync), it is wise to send a few more sync characters ahead of the message (before enabling Transmit CRC) to ensure synchronization at the receiving end.

The Transmit CRC Enable bit can be changed on the fly any time in the message to include or exclude a particular data character from CRC accumulation. The Transmit CRC Enable bit should be in the desired state when the data character is loaded from the transmit shift register. To ensure this bit in the proper state, the Transmit CRC Enable bit must be issued before sending the data character to the MPSC.

Transmit Transparent Mode. Transparent mode (Bisync protocol) operation is made possible by the ability to change Transmit CRC Enable on the fly and by the additional capability of inserting 16 bit sync characters. Exclusion of DLE characters from CRC calculation can be achieved by disabling CRC calculation immediately preceding the DLE character transfer to the MPSC.

reinitialized using the Enable Interrupt On Next Re-

In the transmit mode, the transmitter always sends the programmed number of sync bits (8 or 16) (WR4; D5, D4). When in the Monosync mode, the transmitter sends from WR6 and the receiver compares against WR7. One of two CRC polynomials, CRC 16 or SDLC, may be used with synchronous modes. In the transmit initialization process, the CRC generator is initialized by setting the Reset Transmit CRC Generator command (WR0; D7, D6).

The External/Status interrupt (WR1; D0) mode can be used to monitor the status of the CTS input as well as the Transmit Underrun/EOM latch. Optionally, the Auto Enable (WR3; D5) feature can be used to enable the transmitter when CTS is active. The first data transfer to the MPSC can begin when the External/Status interrupt occurs (CTS (RR0; D5) status bit set) following the Transmit Enable command (WR5; D3).

interrupt whenever a character enters the receive

### Receive

After a channel reset, the receiver is in the Hunt phase, during which the MPSC looks for character synchronization. The Hunt begins only when the receiver is enabled and data transfer begins only when character synchronization has been achieved. If character synchronization is lost, the hunt phase can be re-entered by writing the Enter Hunt Phase (WR3; D4) bit. The assembly of received data continues until the MPSC is reset or until the receiver is

disabled (by command or by  $\overline{\text{CD}}$  while in the Auto Enables mode) or until the CPU sets the Enter Hunt Phase bit. Under program control, all the leading sync characters of the message can be inhibited from loading the receive buffers by setting the Sync Character Load Inhibit (WR3; D1) bit. After character synchronization is achieved the assembled characters are transferred to the receive data FIFO.

Data may be transferred with or without interrupts. Transferring data without interrupts is used for a purely polled operation or for off-line conditions. There are three interrupt modes available for data transfer: Interrupt on First Character Only, Interrupt on Every Character, and Special Receive Conditions Interrupt.

Interrupt on First Character Only mode is normally used to start a polling loop, a block transfer sequence using RDY to synchronize the CPU to the incoming data rate or a DMA transfer using the RxDRQ signal. The MPSC interrupts on the first character and thereafter only interrupts after a Special Receive Condition is detected. This mode can be reinitialized using the Enable Interrupt On Next Receive Character (WR0; D5, D4, D3) command which allows the next character received to generate an interrupt. Parity Errors do not cause interrupts, but End of Frame (SDLC operation) and Receive Overrun do cause interrupts in this mode. If the external status interrupts (WR1; D0) are enabled an interrupt may be generated any time the CD changes state.

Interrupt On Every Character mode generates an interrupt whenever a character enters the receive buffer. Errors and Special Receive Conditions generate a special vector if the Status Affects Vector (WR1B; D2) is selected. Also the Parity Error may be

first data transfer to the MFSC can begin when the

programmed (WR1; D4, D3) not to generate the special vector while in the Interrupt On Every Character mode.

The Special Receive Condition interrupt can only occur while in the Receive Interrupt On First Character Only or the Interrupt On Every Receive Character modes. The Special Receive Condition interrupt is caused by the Receive Overrun (RR1; D5) error condition. The error status reflects an error in the current word in the receive buffer, in addition to any Parity or Overrun errors since the last Error Reset (WR0; D5, D4, D3). The Receive Overrun and Parity error status bits are latched and can only be reset by the Error Reset (WR0; D5, D4, D3) command.

#### SYNCHRONOUS OPERATION—SDLC

#### General

Like the other synchronous operations the SDLC mode must be initialized with the following parameters: SDLC mode (WR4; D5, D4), SDLC polynomial (WR5; D2), Request to Send, Data Terminal Ready, transmit character length (WR5; D6, D5), interrupt modes (WR1; WR2), Transmit Enable (WR5; D3), Receive Enable (WR3; D0), Auto Enable (WR3; D5) and External/Status Interrupt (WR1; D0).WR4 parameters must be written before WR1, WR3, WR5, WR6 and WR7.

The Interrupt modes for SDLC operation are similar to those discussed previously in the synchronous operations section.

#### **Transmit**

After a channel reset, the MPSC begins sending SDLC flags.

Following the flags in an SDLC operation the 8-bit address field, control field and information field may be sent to the MPSC by the microprocessor. The MPSC transmits the Frame Check Sequence using the Transmit Underrun feature. The MPSC automatically inserts a zero after every sequence of 5 consecutive 1's except when transmitting Flags or Aborts.

SDLC—like protocols do not have provision for fill characters within a message. The MPSC therefore automatically terminates an SDLC frame when the transmit data buffer and output shift register have no more bits to send. It does this by sending the two bytes of CRC and then one or more flags. This allows very high-speed transmissions under DMA or CPU control without requiring the CPU to respond quickly to the end-of-message situation.

After a reset, the Transmit Underrun/EOM status bit is in the set state and prevents the insertion of CRC characters during the time there is no data to send. Flag characters are sent. The MPSC begins to send the frame when data is written into the transmit buffer. Between the time the first data byte is written, and the end of the message, the Reset Transmit Underrun/EOM (WR0; D5, D4, D1) command must be issued. The Transmit Underrun/EOM status bit (RR0; D6) is in the reset state at the end of the message which automatically sends the CRC characters.

The MPSC may be programmed to issue a send Abort command (WR0; D5, D4, D3). This command causes at least eight 1's but less than fourteen 1's to be sent before the line reverts to continuous flags.

#### Into the Command/Status Pointer. The reviews

After initialization, the MPSC enters the Hunt phase, and remains in the Hunt phase until the first Flag is received. The MPSC never again enters the Hunt phase unless the microprocessor writes the Enter Hunt command.

or write operation accesses the read or write re-

The MPSC can be programmed to receive all frames or it can be programmed to the Address Search Mode. In the Address Search Mode, only frames with addresses that match the value in WR6 or the global address (0FFH) are received by the MPSC. Extended address recognition must be done by the microprocessor software.

The control and information fields are received as data.

SDLC/HDLC CRC calculation does not have an 8-bit delay, since all characters are included in the calculation, unlike Byte Synchronous Protocols.

Reception of an abort sequence (7 or more 1's) will cause the Break/Abort bit (RR0; D7) to be set and will cause an External/Status interrupt, if enabled. After the Reset External/Status Interrupts Command has been issued, a second interrupt will occur at the end of the abort sequence.

#### **MPSC**

#### **Detailed Command Description**

#### **GENERAL**

The MPSC supports an extremely flexible set of serial and system interface modes.

The system interface to the CPU consists of 8 ports or buffers:

	CS A <sub>0</sub> A <sub>1</sub>		Α,	Read Operation	Write Operation	
	0	0	0.5	Ch. A Data Read	Ch. A Data Write	
	0	0	1	Ch. A Status Read	Ch. A Command/Parameter	
24	0	1	0	Ch. B Data Read	Ch. B Data Write	
-1	0	1	1	Ch. B Status Read	Ch. B Command/Parameter	
H	1	X	X	High Impedence	High Impedence	

Data buffers are addressed by  $A_1 = 0$ , and Command ports are addressed by  $A_1 = 1$ .

Command, parameter, and status information is held in 22 registers within the MPSC (8 write registers and 3 read registers for each channel). They are all accessed via the command ports.

An internal pointer register selects which of the command or status registers will be read or written during a command/status access of an MPSC channel.

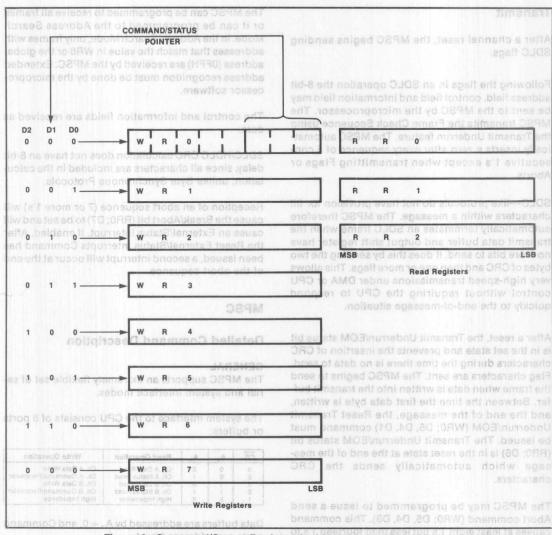

Figure 3. Command/Status Register Architecture (each serial channel)

After reset, the contents of the pointer register are zero. The first write to a command register causes the data to be loaded into Write Register 0 (WR0).

The three least significant bits of WR0 are loaded as the content of the c

Command, parameter, and status information is

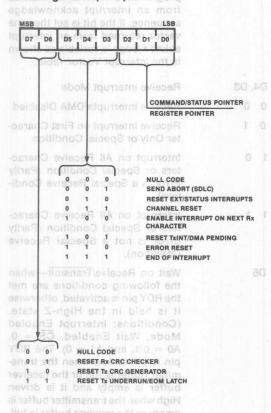

into the Command/Status Pointer. The next read or write operation accesses the read or write register selected by the pointer. The pointer is reset after the read or write operation is completed.

#### COMMAND/STATUS DESCRIPTION

The following command and status bytes are used during initialization and execution phases of operation. All Command/Status operations on the two channels are identical, and independent, except where noted.

#### Write Register 0 (WR0): mas poor

# Detailed Register Description

#### WRO

D2, D1, D0—Command/Status Register Pointer bits determine which write-register the next byte is to be written into, or which read-register the next byte is to be read from. After reset, the first byte written into either channel goes into WR0. Following a read or write to any register (except WR0) the pointer will point to WR0.

D5, D4, D3—Command bits determine which of the basic seven commands are to be performed.

Command 0 Null-has no effect.

Command 1 Send Abort—causes the generation of eight to thirteen 1's when in the SDLC mode.

Command 2 Reset External/Status Interrupts—
resets the latched status bits of
RR0 and re-enables them, allowing
interrupts to occur again.

Command 3

Channel Reset—resets the Latched Status bits of RR0, the interrupt prioritization logic and all control registers for the channel. Four extra system clock cycles should be allowed for MPSC reset time before any additional commands or controls are written into the channel.

Command 4 Enable Interrupt on Next Receive Character—if the Interrupt on First Receive Character mode is selected, this command reactivates that mode after each complete message is received to prepare the MPSC for the next message.

Command 5

Reset Transmitter Interrupt/DMA

Pending—if The Transmit
Interrupt/DMA Enable mode is
selected, the MPSC automatically
interrupts or requests DMA data
transfer when the transmit buffer
becomes empty. When there are no
more characters to be sent,
issuing this command prevents
further transmitter interrupts or
DMA requests until the next
character has been completely
sent.

Command 6 Fror Reset—error latches, Pari-UO and no and ty and Overrun errors in RR1 are

Command 7 End of Interrupt—resets the interrupt-in-service latch of the highest-priority internal device under service.

D7, D6 CRC Reset Code

Null—has no effect.

01 Reset Receive CRC Checker—
resets the CRC checker to 0's. If in
SDLC mode the CRC checker is
initialized to all 1's.

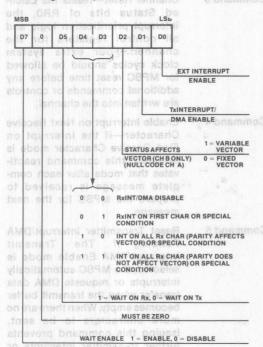

Deoxe , inebne

10 Reset Transmit CRC Generator
—resets the CRC generator to
0's. If in SDLC mode the CRC
generator's initialized to all 1's.

11 Reset Tx Underrun/End of Message Latch.

#### Write Register 1 (WR1):

D0 External/Status Interrupt Enable
—allows interrupt to occur as the
result of transitions on the CD,
CTS or SYNDET inputs. Also
allows interrupts as the result of a
Break/Abort detection and termination, or at the beginning of CRC,
or sync character transmission
when the Transmit Underrun/EOM
latch becomes set.

D1 Transmitter Interrupt/DMA Enable
beautiful and a service —allows the MPSC to interrupt or
request a DMA transfer when the
transmitter buffer becomes empty.

Status Affects vector—(WR1, D2 active in channel B only.) If this bit is not set, then the fixed vector, programmed in WR2, is returned from an interrupt acknowledge sequence. If the bit is set then the vector returned from an interrupt acknowledge is variable as shown in the Interrupt Vector Table.

D4, D3 Receive Interrupt Mode

0 0 Receive Interrupts/DMA Disabled

0 1 Receive Interrupt on First Character Only or Special Condition

1 0 Interrupt on All Receive Charac-

O Interrupt on All Receive Characters or Special Condition (Parity Error is a Special Receive Condition)

Interrupt on All Receive Characters or Special Condition (Parity Error is not a Special Receive Condition).

D5 Wait on Receive/Transmit-when the following conditions are met the RDY pin is activated, otherwise it is held in the High-Z state. (Conditions: Interrupt Enabled Mode, Wait Enabled,  $\overline{CS} = 0$ , A0 = 0/1, and A1 = 0). The RDY pin is pulled low when the transmitter buffer is full or the receiver buffer is empty and it is driven High when the transmitter buffer is empty or the receiver buffer is full. The RDYA and RDYB may be wired OR connected since only one signal is active at any one time while the other is in the High Z state.

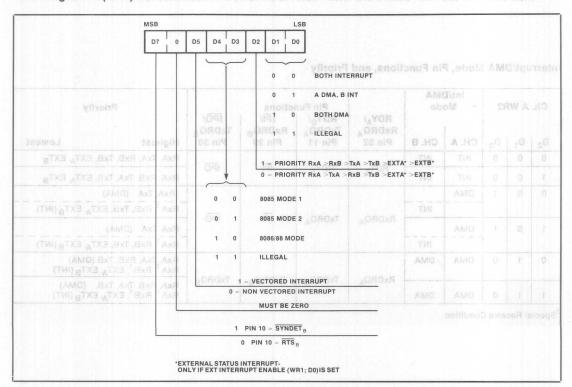

6 Must be Zero

D7: sixd xsn of Wait Enable—enables the wait one neith were function.

#### Write Register 5 (WR5):

- I stop bit/character

  I-½ stop bits/character

  Stop bits/character
  - buffer into the shift register. A zero in this bit disables CRC calculations. If this bit is not set when a transmitter underrun occurs, the CRC will not be sent.
  - D1 Request to Send—a one in this bit forces the RTS pin active (low) and zero in this bit forces the RTS pin inactive (high).
  - D2 CRC Select—a one in this bit selects the CRC -16 polynomial ( $X^{16} + X^{15} + X^2 + 1$ ) and a zero in this bit selects the CCITT-CRC polynomial ( $X^{16} + X^{15} + X^5 + 1$ ).
  - D3 Transmitter Enable—a zero in this bit forces a marking state on the transmitter output. If this bit is set to zero during data or sync character transmission, the marking state is entered after the character has been sent. If this bit is set to zero during transmission of a CRC character, sync or flag bits are substituted for the remainder of the CRC bits.
  - D4 Send Break—a one in this bit forces the transmit data low. A one in this bit allows normal transmitter operation.
  - D6, D5 Transmit Character length
  - 0 0 Transmit 5 or less bits/character
  - 0 1 Transmit 7 bits/character
  - 1 0 Transmit 6 bits/character
  - 1 1 Transmit 8 bits/character

Bits to be sent must be right justified least significant bit first, eq:

D7 D6 D5 D4 D3 D2 D1 D0

0 0 B5 B4 B3 B2 B1 B0

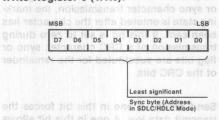

Five or less mode allows transmission of one to five bits per manys absided and aim and a —a character. The microprocessor must format the data in additional the following way:

	D6				D2	D1	D0	ync mode.) 1-1/2 stop bits/character
	ne sh CRC				1	1	В0	Sends one data bit
	onen a				0	В1	В0	Sends two data bits
1	1 bns2	0	0	0	B2	B1	В0	Sends three data bits
q) s	0	0	0	В3				Sends four data bits
0	0	0	B4	ВЗ	B2	B1	В0	Sends five data bits

Data Terminal Ready—when set, this bit forces the DTR pin active (low). When reset, this bit forces the DTR pin inactive

#### Write Register 7 (WR7):

#### WR6

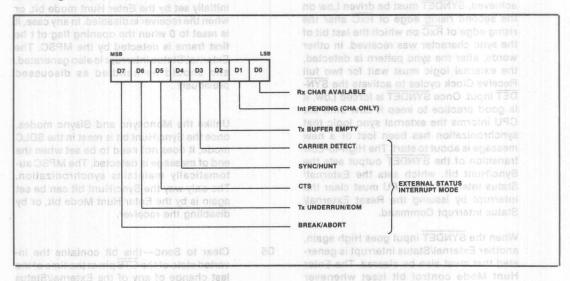

D7-D0 Sync/Address—this register contains the transmit sync character in Monosync mode, the low order 8 sync bits in Bisync mode, or the Address byte in SDLC mode.

WR7

D7-D0 Sync/Flag—this register contains the receive sync character in Monosync mode, the high order 8 sync bits in Bisync mode, or the Flag character (01111110) in SDLC mode. WR7 is not used in External Sync mode.

#### Read Register 0 (RR0): born 0.102 sdf al

#### bits (CD, CTS, Sync/Hunt, Break/Abortonn

- DO Receive Character Available—this bit is set when the receive FIFO contains data and is reset when the FIFO is empty.
- D1 Interrupt Pending\*—This Interrupt-Pending bit is reset when an EOI command is issued and there is no other interrupt request pending at that time.
- D2 Gas Transmit Buffer Empty—This bit is set whenever the transmit buffer is empty except when CRC characters are being sent in a synchronous mode. This bit is G.OFF reset when the transmit buffer is loaded. This bit is set after an MPSC reset.
- Carrier Detect—This bit contains the state of the CD pin at the time of the last change of any of the External/Status bits (CD, CTS, Sync/Hunt, Break/Abort, or Tx Underrun/EOM). Any change of state of the CD pin causes the CD bit to be latched and causes an External/Status interrupt. This bit indicates current state of the CD pin immediately following a Reset External/Status Interrupt command.

\*In vector mode this bit is set at the falling edge of the second INTA in an INTA cycle for an internal interrupt request. In non-vector mode, this bit is set at the falling edge of RD input after pointer 2 is specified. This bit is always zero in Channel B. D4 Sync/Hunt-In asynchronous modes, the operation of this bit is similar to the CD status bit, except that Sync/Hunt shows the state of the SYNDET input. Any High-to-Low transition on the SYNDET pin sets this bit, and causes an External/Status interrupt (if enabled). The Reset External/Status Interrupt command is issued to clear the interrupt. A Low-to-High transition clears this bit and sets the External/Status interrupt. When the External/Status interrupt is set by the change in state of any other input or condition, this bit shows the inverted state of the SYNDET pin at time of the change. This bit must be read immediately following a Reset External/Status Interrupt command to read the current state of the SYNDET input.

In the External Sync mode, the Sync/Hunt bit operates in a fashion similar to the Asynchronous mode, except the Enter Hunt Mode control bit enables the external sync detection logic. When the External Sync Mode and Enter Hunt Mode bits are set (for example, when the receiver is enabled following a reset), the SYNDET input must be held High by the external logic until external character synchronization is achieved. A High at the SYNDET input holds the Sync/Hunt status in the reset condition.

When external synchronization is achieved, SYNDET must be driven Low on the second rising edge of RxC after the rising edge of RxC on which the last bit of the sync character was received. In other words, after the sync pattern is detected, the external logic must wait for two full Receive Clock cycles to activate the SYN-DET input. Once SYNDET is forced Low, it is good practice to keep it Low until the CPU informs the external sync logic that synchronization has been lost or a new message is about to start. The High-to-Low transition of the SYNDET output sets the Sync/Hunt bit, which sets the External/ Status interrupt. The CPU must clear the interrupt by issuing the Reset External/ Status Interrupt Command.

When the SYNDET input goes High again, another External/Status interrupt is generated that must also be cleared. The Enter Hunt Mode control bit isset whenever character synchronization is lost or the end of message is detected. In this case, the MPSC again looks for a High-to-Low transition on the SYNDET input and the operation repeats as explained previously. This implies the CPU should also inform the external logic that character synchronization has been lost and that the MPSC is waiting for SYNDET to become active.

In the Monosync and Bisync Receive modes, the Sync/Hunt status bit is initially set to 1 by the Enter Hunt Mode bit. The Sync/Hunt bit is reset when the MPSC establishes character synchronization. The High-to-Low transition of the Sync/Hunt bit causes an External/Status interrupt that must be cleared by the CPU issuing the Reset External/Status Interupt command. This enables the MPSC to detect the next transition of other External/Status bits.

When the CPU detects the end of message or that character synchronization is lost, it sets the Enter Hunt Mode control bit, which sets the Sync/Hunt bit to 1. The Low-to-High transition of the Sync/Hunt bit sets the External/Status Interrupt, which must also be cleared by the Reset External/Status Interrupt Command. Note that the SYNDET pin acts as an output in this mode, and goes low every time a sync pattern is detected in the data stream.

In the SDLC mode, the Sync/Hunt bit is initially set by the Enter Hunt mode bit, or when the receiver is disabled. In any case, it is reset to 0 when the opening flag of t he first frame is detected by the MPSC. The External/Status interrupt is also generated, and should be handled as discussed previously.

Unlike the Monosync and Bisync modes, once the Sync/Hunt bit is reset in the SDLC mode, it does not need to be set when the end of message is detected. The MPSC automatically maintains synchronization. The only way the Sync/Hunt bit can be set again is by the Enter Hunt Mode bit, or by disabling the receiver.

- Clear to Send—this bit contains the inverted state of the CTS pin at the time of the last change of any of the External/Status bits (CD, CTS, Sync/Hunt, Break/Abort, or Tx Underrun/EOM). Any change of state of the CTS pin causes the CTS bit to be latched and causes an External/Status interrupt. This bit indicates the inverse of the current state of the CTS pin immediately following a Reset External/Status Interrupt command.
- D6 Transmitter Underrun/End of Message—this bit is in a set condition following a reset (internal or external). The only command that can reset this bit is the Reset Transmit Underrun/EOM Latch command (WR0,  $D_6$  and  $D_7$ ). When the Transmit Underrun condition occurs, this bit is set, which causes the External/Status Interrupt which must be reset by issuing a Reset External/Status command (WR0; command 2).
- Break/Abort—in the Asynchronous Receive mode, this bit is set when a Break sequence (null character plus framing error) is detected in the data stream. The External/Status interrupt, if enabled, is set when break is detected. The interrupt service routine must issue the Reset External/Status Interrupt command (WRO, Command 2) to the break detection logic so the Break sequence termination can be recognized.

#### SDLC Residue Code Table (I Field Bits in 2 Previous Bytes) (1947) I relation been

			8 bit	s/char	7 bits	s/char	6 bits	s/char	5 bits/char	
RR1 D3, D2, D1			Previous Byte	2nd Prev. Byte	Previous Byte	2nd Prev. Byte	Previous Byte	2nd Prev. Byte	Previous Byte	2nd Prev. Byte
1	0	0	0	3		LACLISHET				
0	1	0	0	4			0	6		
1	1	0	0	5	I FIELD SITS	ETIG DIER				
0	0	1	0	6	2ND PREVIOUS B	STAR SOCIATION OF THE START OF	0.00		0	5
1	0	1	0	7						
0	1	1	0	8						
1	1	1	1	8			0.1.0			
0	0	0	2	ATAGSUGISSA	8 0	7	7 7 0			

The Break/Abort bit is reset when the termination of the Break sequence is detected in the incoming data stream. The termination of the Break sequence also causes the External/Status interrupt to be set. The Reset External/Status Interrupt command must be issued to enable the break detection logic to look for the next Break sequence. A single extraneous null character is present in the receiver after the termination of a break; it should be read and discarded.

In the SDLC Receive mode, this status bit is a vine set by the detection of an Abort sequence bileves is (seven or more 1's). The External/Status is identification interrupt is handled the same way as in the brisming case of a Break. The Break/Abort bit is not respective mode.

DO All sent—this bit is set when all characters have been sent, in asynchronous modes. It is reset when characters are in the transmitter, in asynchronous modes. In synchronous modes, this bit is always set.

D3, D2, D1 Residue Codes—bit synchronous protocols allow I-fields that are not an interior in deligral number of characters. Since transmed and offers from the MPSC to the CPU are characters oriented, the residue codes be negligible provide the capability of receiving revolute leftover bits. Residue bits are right justice to the last two data bytes received.

D4 m at 3 Parity Error—If parity is enabled, this bit number and is set for received characters whose parallibration ity does not match the programmed sense (Even/Odd). This bit is latched. Once an error occurs, it remains set until statement of the Error Reset command is written.

#### D7 D6 D5 D4 D3 D2 D1 DO Byte Byte L ALL SENT I FIELD BITS 2ND PREVIOUS BYTE I FIELD BITS PREVIOUS BYTE 2 8 0 0 0 0 0 1 0 1 1 8 RESIDUE DATA 8 BITS/CHAR, MODE 1 0 0 0 3 1 0 1 1 1 0 5 1 1 1 The Break/Abort bit is reset who some Yang ters have bee Rx OVERRUN ERROR MASS Stream RORRE IN INC. modes, it is re-CRC/FRAMING ERROR & SOME UDGS NEST S BITTED HOLD END OF FRAME (SDLC/HDLC MODE)

#### Read Register 1 (RR1): (Special Receive Condition Mode) de l'about subles R 0108

D5 Receive Overrun Error—this bit indi-

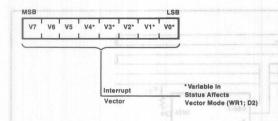

cates that the receive FIFO has been asboo all overloaded by the receiver. The last character in the FIFO is overwritten and flagged with this error. Once the overbevisces written character is read, this error condition is latched until reset by the Error Reset command. If the MPSC is in the status affects vector mode, the overrun bemman ocauses a special Receive Condition sense (Even/Odd). TrotoeV is latched.

D6 CRC/Framing Error—In async modes, a one in this bit indicates a receive fram-saimed oring error. In synchronous modes, a one in this bit indicates that the calculated CRC value does not match the last two bytes received. It can be reset by issuing an Error Reset command.

D7 End of Frame—this bit is valid only in SDLC mode. A one indicates that a valid ending flag has been received. This bit is ton all lid preset either by an Error Reset command or upon reception of the first character of the next frame.

#### Read Register 2 (RR2):

#### RR2 Channel B

D7-D0 Interrupt vector—contains the interrupt vector programmed into WR2. If the status affects vector mode is selected, it contains the modified vector. (See WR2) RR2 contains the modified vector for the highest priority interrupt pending. If no interrupts are pending, the variable bits in the vector are set to one.

#### SYSTEM INTERFACE

General near the conditions in each chan larene The MPSC to Microprocessor System interface can be configured in many flexible ways. The basic interface types are polled, wait, interrupt driven, or direct memory access driven. nerto dose not tesuper to in

Polled operation is accomplished by repetitively reading the status of the MPSC, and making decisions based on that status. The MPSC can be polled at any time, stanois event to vinoing ent. elampia

Wait operation allows slightly faster data throughput for the MPSC by manipulating the Ready input to the microprocessor. Block Read or Write Operations to the MPSC are started at will by the microprocessor and the MPSC deactivates its RDY signal if it is not yet ready to transmit the new byte, or if reception of new byte is not completed.

Interrupt driven operation is accomplished via an internal or external interrupt controller. When the MPSC requires service, it sends an interrupt request signal to the microprocessor, which responds with an interrupt acknowledge signal. When the internal or external interrupt controller receives the acknowledge, it vectors the microprocessor to a service routine, in which the transaction occurs. DMA operation is accomplished via an external DMA controller. When the MPSC needs a data transfer, it request a DMA cycle from the DMA controller. The DMA controller then takes control of the bus and simultaneously does a read from the MPSC and a write to memory or vice-versa.

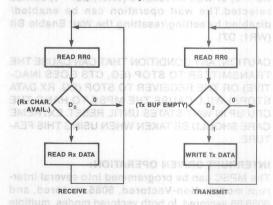

The following section describes the many configurations of these basic types of system interface techniques for both serial channels.

#### Polled Operation:

In the polled mode, the CPU must monitor the desired conditions within the MPSC by reading the appropriate bits in the read registers. All data available. status, and error conditions are represented by the appropriate bits in read registers 0 and 1 for channels A and B.

There are two ways in which the software task of monitoring the status of the MPSC has been reduced. One is the "ORing" of all conditions into the Interrupt Pending bit. (RR0; D1 channel A only). This bit is set when the MPSC requires service, allowing the CPU to monitor one bit instead of four status registers. The other is available when the "statusaffects-vector" mode is selected. By reading RR2 Channel B, the CPU can read a vector who's value will indicate that one or more of group of conditions has occurred, narrowing the field of possible conditions. See WR2 and RR2 in the Detailed Command Description section.

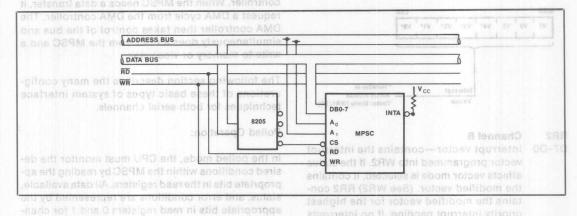

#### Software Flow, Polled Operation New 10 10 = 20

Interrupt acknowledge sequence by placing a call

#### Hardware Configuration, Polled Operation AMO

#### WAIT OPERATION:

Wait Operation is intended to facilitate data transmission or reception using block move operations. If a block of data is to be transmitted, for example, the CPU can execute a String I/O instruction to the MPSC. After writing the first byte, the CPU will attempt to write a second byte immediately as is the case of block move. The MPSC forces the RDY signal low which inserts wait states in the CPU's write cycle until the transmit buffer is ready to accept a new byte. At that time, the RDY signal is high allowing the CPU to finish the write cycle. The CPU then attempts the third write and the process is repeated.

Similar operation can be programmed for the receiver. During initialization, wait on transmit (WR2; D5 = 0) or wait on receive (WR1; D5 = 1) can be selected. The wait operation can be enabled/disabled by setting/resetting the Wait Enable Bit (WR1; D7).

CAUTION: ANY CONDITION THAT CAN CAUSE THE TRANSMITTER TO STOP (EG, CTS GOES INACTIVE) OR THE RECEIVER TO STOP (EG, RX DATA STOPS) WILL CAUSE THE MPSC TO HANG THE CPU UP IN WAIT STATES UNTIL RESET. EXTREME CARE SHOULD BE TAKEN WHEN USING THIS FEATURE.

#### INTERRUPT DRIVEN OPERATION:

The MPSC can be programmed into several interrupt modes: Non-Vectored, 8085 vectored, and 8088/86 vectored. In both vectored modes, multiple MPSC's can be daisy-chained.

In the vectored mode, the MPSC responds to an interrupt acknowledge sequence by placing a call instruction (8085 mode) and interrupt vector (8085

and 8088/86 mode) on the data bus. In the non-vectored mode, the MPSC does not respond to INTA sequences and must rely on an external interrupt controller such as the 8259A.

The MPSC can be programmed to cause an interrupt due to up to 14 conditions in each channel. The status of these interrupt conditions is contained in Read Registers 0 and 1. These 14 conditions are all directed to cause 3 different types of internal interrupt request for each channel: receive/interrupts, transmit interrupts and external/status interrupts (if enabled).

This results in up to 6 internal interrupt request signals. The priority of those signals can be programmed to one of two fixed modes:

of thighest Priority all Lowest Priority of the of another of the Orange of the Orange

RXA RXB TXA TXB EXTA EXTB

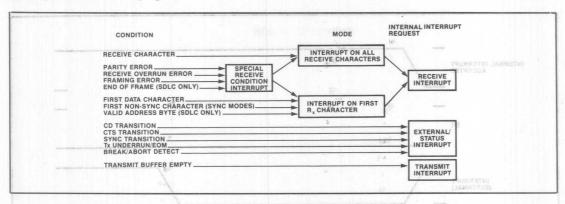

The interrupt priority resolution works differently for vectored and non-vectored modes.

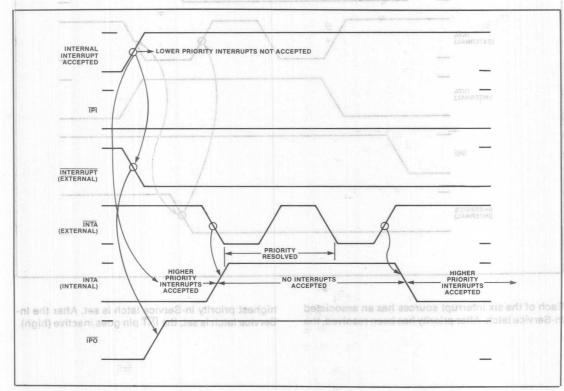

#### PRIORITY RESOLUTION: VECTORED MODE

Any interrupt condition can be accepted internally to the MPSC at any time, unless the MPSC's internal INTA signal is active, unless a higher priority interrupt is currently accepted, or if IPI is inactive (high). The MPSC's internal INTA is set on the leading (falling) edge of the first External INTA pulse and reset on the trailing (rising) edge of the second External INTA pulse. After an interrupt is accepted internally, an External INT request is generated and the IPO goes inactive. IPO and IPI are used for daisy-chaining MPSC's together.

#### **Interrupt Condition Grouping**

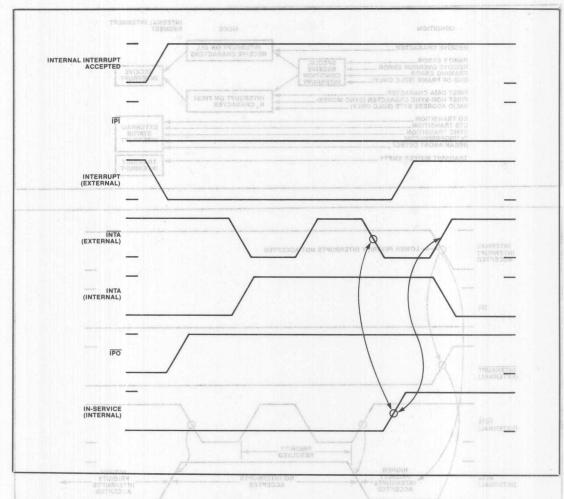

The MPSC's internal INTA is set on the leading (falling) edge of the first external INTA pulse, and reset on the trailing (rising) edge of the second external INTA pulse. After an interrupt is accepted internally,

an external  $\overline{\text{INT}}$  request is generated and  $\overline{\text{IPO}}$  goes inactive (high).  $\overline{\text{IPO}}$  and  $\overline{\text{IPI}}$  are used for daisy-chaining MPSC's together.

#### **In-Service Timing**

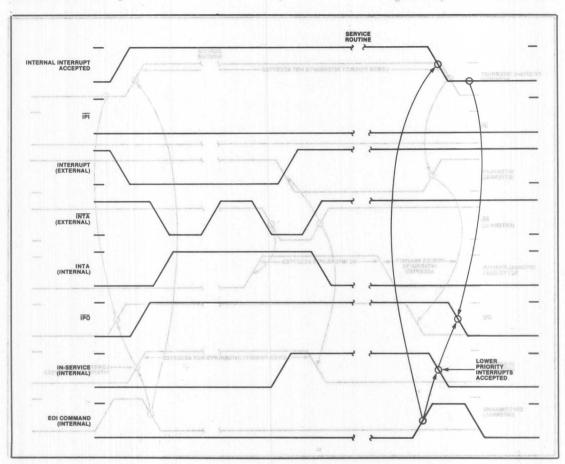

Each of the six interrupt sources has an associated In-Service latch. After priority has been resolved, the

highest priority In-Service latch is set. After the In-Service latch is set, the INT pin goes inactive (high).

an external INT request is generated and IPO goes inactive (high). IPO and IPi are used for darsychaining MPSC's together.

The MPSC's internal INTA is set on the leading (falling) edge of the first external INTA pulse, and reset on the trailing (rising) edge of the second external INTA pulse. After an interrupt is accepted internally.

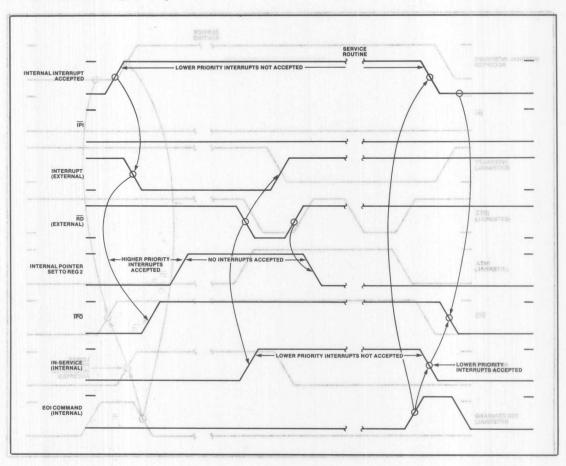

Lower priority interrupts are not accepted internally while the In-Service latch is set. However, higher priority interrupts are accepted internally and a new external INT request is generated. If the CPU responds with a new INTA sequence, the MPSC will respond as before, suspending the lower priority

ing edge of the read signal used by th.tqurretnic retrieve the modified vector. The leading edge of read sets the in-Service latch and forces the external INT output inactive (high). The internal pointer is reset to zero after the trailing edge of the read pulse.

After the interrupt is serviced, the End-of-Interrupt (EOI) command should be written to the MPSC. This command will cause an internal pulse that is used to reset the In-Service Latch which allows service for lower priority interrupts in the daisy-chain to resume, provided a new INTA sequence does not start for a higher priority interrupt (higher than the highest under service). If there is no interrupt pending internally, the IPO follows IPI.

#### **Non-Vectored Interrupt Timing**

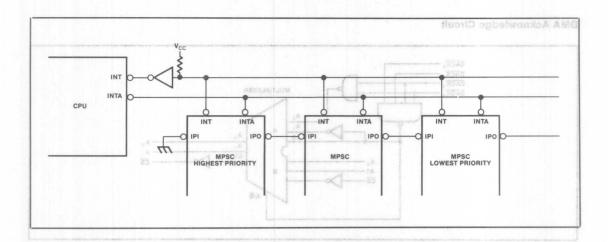

### PRIORITY RESOLUTION: is all further the first the street of the street o

In non-vectored mode, the MPSC does not respond to interrupt acknowledge sequences. The MPSC should be programmed to the Status-Affects-Vector mode, and the CPU should read RR2 (Ch. B) in its service routine to determine which interrupt requires service.

In this case, the internal pointer being set to RR2 provides the same function as the internal INTA signal in the vectored mode. It inhibits acceptance of any additional internal interrupts and its leading edge starts the interrupt priority resolution circuit. The interrupt priority resolution is ended by the leading edge of the read signal used by the CPU to retrieve the modified vector. The leading edge of read sets the In-Service latch and forces the external INT output inactive (high). The internal pointer is reset to zero after the trailing edge of the read pulse.

Note that if RR2 is specified but not read, no internal interrupts, regardless of priority, are accepted.

#### DAISY CHAINING MPSC:

In the vectored interrupt mode, multiple MPSC's can be daisy-chained on the same INT, INTA signals. These signals, in conjunction with the IPI and IPO allow a daisy-chain-like interrupt resolution scheme. This scheme can be configured for either 8085 or 8086/88 based system.

In either mode, the same hardware configuration is called for. The INT request lines are wire-OR'ed together at the input of a TTL inverter which drives the INT pin of the CPU. The INTA signal from the CPU drives all of the daisy-chained MPSC's.

The MPSC drives IPO (Interrupt Priority Output) inactive (high) if IPI (Interrupt Priority Input) is inactive (high), or if the MPSC has an interrupt pending.

The  $\overline{\text{IPO}}$  of the highest priority MPSC is connected to the  $\overline{\text{IPI}}$  of the next highest priority MPSC, and so on.

Wait Interrupt Polled	Walt Interrupt Polled	0.0	
	DMA Polled	1.0	
DMA Polled	DMA: Polled	1.0	

D1, D0 = 1, 1 is illegal.

If  $\overline{|P|}$  is active (low), the MPSC knows that all higher priority MPSC's have no interrupts pending. The  $\overline{|P|}$  pin of the highest priority MPSC is strapped active (low) to ensure that it always has priority over the rest.

MPSC's Daisy-chained on an 8088/86 CPU should be programmed to the 8088/86 Interrupt mode (WR2; D4, D3 (Ch. A). MPSC's Daisy-chained on an 8085 CPU should be programmed to 8085 interrupt mode 1 if it is the highest priority MPSC. In this mode, the highest priority MPSC issues the CALL instruction during the first INTA cycle, and the interrupting MPSC provides the interrupt vector during the following INTA cycles. Lower priority MPSC's should be programmed to 8085 interrupt mode 2.

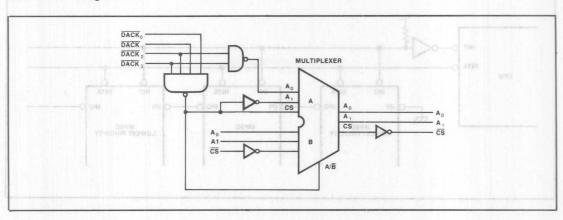

MPSC's used alone in 8085 systems should be programmed to 8085 mode 1 interrupt operation.

by encoding the  $\overline{\rm DACK}$  signals to generate  ${\rm A_0},{\rm A_1},$  and  $\overline{\rm CS}$  signals, and multiplexing them with the normal  ${\rm A_0},{\rm A_1}$  and  $\overline{\rm CS}$  signals.

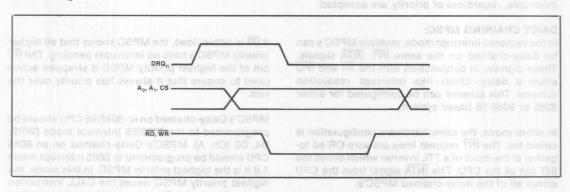

PERMUTATIONS

Channels A and B can be used with different system interface modes. In all cases it is impossible to poll the MPSC. The following table shows the possible.

# Jint Actiowieuge Circuit

#### **DMA Timing**

### MPSC provides the interrupt ve NOITRARAGO AMO

Each MPSC can be programmed to utilize up to four DMA channels: Transmit Channel A, Receive Channel A, Transmit Channel B, Receive Channel B. Each DMA Channel has an associated DMA Request line. Acknowledgement of a DMA cycle is done via normal data read or write cycles. This is accomplished by encoding the  $\overline{\rm DACK}$  signals to generate A<sub>0</sub>, A<sub>1</sub>, and  $\overline{\rm CS}$  signals, and multiplexing them with the normal A<sub>0</sub>, A<sub>1</sub>, and  $\overline{\rm CS}$  signals.

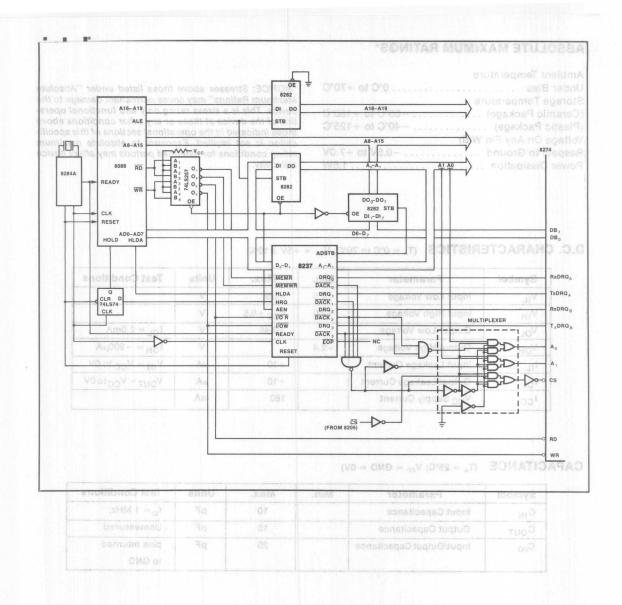

#### **PERMUTATIONS**

Channels A and B can be used with different system interface modes. In all cases it is impossible to poll the MPSC. The following table shows the possible

permutations of interupt, wait, and DAM modes for channels A and B. Bits  $D_1$ ,  $D_0$  of WR2 Ch. A determine these permutations.

Permutation WR2 Ch. A D <sub>1</sub> D <sub>0</sub>	Channel A	Channel B
0 0	Wait Interrupt Polled	Wait Interrupt Polled
0 1	DMA Polled	Interrupt Polled
1 0	DMA Polled	DMA Polled

D1, D0 = 1, 1 is illegal.

The 8291A is an enhanced version of the 8291 GPIB Talker/Listener designed to interface microprocessors to an IEEE Standard 488 Instrumentation Interface Bus. It implements all of the Standard's interface functions except for the controller. The controller function can be added with the 8292 GPIB Controller, and the 8293 GPIB Transceiver performs the electrical interface for Talker/Listener and Talker/Listener/Controller configurations.

as stubsoom noites! Figure 1. Block Diagram

owt no non agassam Figure 2. Pin Configuration

The 8291A is an improved design of the 8291 GPIB Talker/Listener. Most of the functions are identical to the 8291, and the pin configuration is unchanged.

The 8291A offers the following improvements to the

- 1. EOI is active with the data as a ninth data bit rather than as a control bit. This is to comply with some additions to the 1975 IEEE-488 Standard incorporated in the 1978 Standard.
- 2. The BO interrupt is not asserted until RFD is true. If the Controller asserts ATN synchronously, the data is guaranteed to be transmitted. If the Controller asserts ATN asynchronously, the SH (Source Handshake) will return to SIDS (Source Idle State), and the output data will be cleared. The, if ATN is released while the 8291A is addressed to talk, a new BO interrupt will be generated. This change fixes 8291 problems which caused data to be lost or repeated and a problem with the RQS bit (sometimes cannot be asserted while talking).
- 3. LLOC and REMC interrupts are setting flipflops rather than toggling flipflops in the interrupt backup register. This ensures that the CPU knows that these state changes have occurred. The actual state can be determined by checking the LLO and REM status bits in the upper nibble of the Interrupt Status 2 Register.
- 4. DREQ is cleared by DACK (RD + WR). DREQ on the 8291 was cleared only by DACK which is not compatible with the 8089 I/O Processor.
- 5. The INT bit in Interrupt Status 2 Register is duplicated in bit 7 of the Address 0 Register. If software polling is used to check for an interrupt, INT in the Address 0 Register should be polled rather than the Interrupt Status 2 Register. This ensures that no interrupts are lost due to asynchronous status reads and interrupts.
- 6. The 8291A's Send EOI Auxiliary Command works on any byte including the first byte of a message. The 8291 did not assert EOI after this command for a one byte message nor on two consecutive bytes.

- 8291A FEATURES AND IMPROVEMENTS 7. To avoid confusion between holdoff on DAV versus RFD if a device is readdressed from a talker to a listener role or vice-versa during a holdoff, the "Holdoff on Source Handshake" has been eliminated. Only "Holdoff on Acceptor Handshake" is available.
  - 8. The rsv local message is cleared automatically upon exit from SPAS if (APRS.STRS.SPAS) occurred. The automatic resetting of the bit after the serial poll is complete simplifies the service request software.
  - 9. The SPASC interrupt on the 8291 has been replaced by the SPC (Serial Poll Complete) interrupt on the 8291A. SPC interrupt is set on exit from SPAS if APRS.STRS.SPAS occurred, indicating that the controller has read the bus status byte after the 8291A requested service. The SPASC interrupt was ambiguous because a controller could enter SPAS and exit SPAS generating two SPASC interrupts without reading the serial poll status byte. The SPC interrupt also simplifies the CPU's software by eliminating the interrupt when the serial poll is half way done.
  - 10. The rtl Auxiliary Command in the 8291 has been replaced by Set and Clear rtl Commands in the 8291A. Using the new commands, the CPU has the flexibility to extend the length of local mode or leave it as a short pulse as in the 8291.
  - 11. A holdoff RFD on GET, SDC, and DCL feature has been added to prevent additional bus activity while the CPU is responding to any of these commands. The feature is enabled by a new bit (B4) in the Auxiliary Register B.
  - 12. On the 8291, BO could cease to occur upon IFC going false if IFC occurred asynchronously. On the 8291A, BO continues to occur after IFC has gone false even if it arrived asynchronously.
  - 13. User's software can distinguish between the 8291 and the 8291A as follows:
    - a) pon (00H to register 5)
    - b) RESET (02H to register 5)
    - c) Read Interrupt Status 1 Register. If BO interrupt is set, the device is the 8291. If BO is clear, it is the 8291A.

This can be used to set a flag in the user's software which will permit special routines to be executed for each device. It could be included as part of a normal initialization procedure as the first step after a chip reset.

#### NOTE:

All signals on the 8291A pins are specified with positive logic. However, IEEE 488 specifies negative logic on its 16 signal lines. Thus, the data is inverted once from  $D_0-D_7$  to  $\overline{DIO}_0-\overline{DIO}_8$  and non-inverting bus transceivers should be used.

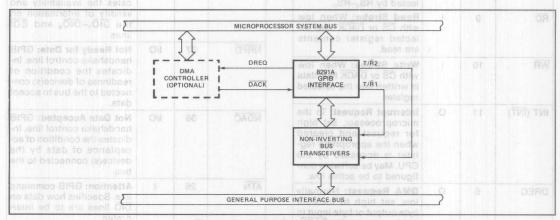

Figure 3. 8291A System Diagram

# THE GENERAL PURPOSE INTERFACE BUS (GPIB)

The General Purpose Interface Bus (GPIB) is defined in the IEEE Standard 488-1978 "Digital Interface for Programmable Instrumentation." Although a knowledge of this standard is assumed, Figure 4 provides the bus structure for quick reference. Also, Tables 2 and 3 reference the interface state mnemonics and the interface messages respectively. Modified state diagrams for the 8291A are presented in Appendix A.

#### **General Description**

The 8291A is a microprocessor-controlled device designed to interface microprocessors, e.g., 8048/49, 8051, 8080/85, 8086/88 to the GPIB. It implements all of the interface functions defined in the

IEEE-488 Standard except for the controller function. If an implementation of the Standard's Controller is desired, it can be connected with an Intel® 8292 to form a complete interface.

The 8291A handles communication between a microprocessor-controlled device and the GPIB. Its capabilities include data transfer, handshake protocol, talker/listener addressing procedures, device clearing and triggering, service request, and both serial and parallel polling. In most procedures, it does not disturb the microprocessor unless a byte has arrived (input buffer full) or has to be sent out (output buffer empty).

The 8291A architecture includes 16 registers. Eight of these registers may be written into by the microprocessor. The other eight registers may be read by the microprocessor. One each of these read and

write registers is for direct data transfers. The rest of the write registers control the various features of the chip, while the rest of the read registers provide the microprocessor with a monitor of GPIB states, various bus conditions, and device conditions.

# **GPIB Addressing**

Each device connected to the GPIB must have at least one address whereby the controller device in charge of the bus can configure it to talk, listen, or send status. An 8291A implementation of the GPIB offers the user three alternative addressing modes for which the device can be initialized for each application. The first of these modes allows for the device to have two separate primary addresses. The second mode allows the user to implement a single talker/listener with a two byte address (primary address + secondary address). The third mode again allows for two distinct addresses but in this instance, they can each have a ten-bit address (5 low-order bits of each of two bytes). However, this mode requires that the secondary addresses be passed to the microprocessor for verification. These three addressing schemes are described in more detail in the discussion of the Address Registers.

3. All Controller messages must be sent via Intel's 8292.

# 8291A Registers

A bit-by-bit map of the 16 registers on the 8291A is presented in Figure 5. A more detailed explanation of each of these registers and their functions follows. The access of these registers by the microprocessor is accomplished by using the CS, RD, WR, and RSo-RS2 pins.

Register	CS	RD	WR	RS <sub>0</sub> -RS <sub>2</sub>	
All Read Registers	0	0	. 1	CCC	
All Write Registers	0	1	0	CCC

# Data Registers

DI7 DI6 DI5 DI4 DI3 DI2 DI1 DI0

DATA-IN REGISTER (OR)

DO7 DO6 DO5 DO4 DO3 DO2 DO1 DO0

DATA-OUT REGISTER (0W)

The Data-In Register is used to move data from the GPIB to the microprocessor or to memory when the 8291A is addressed to listen. Incoming information is separately latched by this register, and its contents are not destroyed by a write to the data-out

register. The RFD (Ready for Data) message is held false until the byte is removed from the data in register, either by the microprocessor or by DMA. The 8291A then completes the handshake automatically. In RFD holdoff mode (see Auxiliary Register A), the handshake is not finished until a command is sent telling the 8291A to release the holdoff. In this way, the same byte may be read seveal times, or an over anxious talker may be held off until all available data has been processed.

When the 8291A is addressed to talk, it uses the data-out register to move data onto the GPIB. After the BO interrupt is received and a byte is written to this register, the 8291A initiates and completes the handshake while sending the byte out over the bus. In the BO interrupt disable mode, the user should wait until BO is active before writing to the register. (In the DMA mode, this will happen automatically.) A read of the Data-In Register does not destroy the information in the Data-Out Register.

The 8291A can be configured to generate an interrupt to the microprocessor upon the occurrence of any of 12 conditions or events on the GPIB. Upon receipt of an interrupt, the microprocessor must read the Interrupt Status Registers to determine which event has occurred, and then execute the appropriate service routine (if necessary). Each of the 12 interrupt status bits has a matching enable bit in the interrupt enable registers. These enable bits are used to select the events that will cause the INT pin to be asserted. Writing a logic "1" into any of these bits enables the corresponding interrupt status bits to generate an interrupt. Bits in the Interrupt Status Registers are set regardless of the states of the enable bits. The Interrupt Status Registers are then cleared upon being read or when a local pon-(power-on) message is executed. If an event occurs while one of the Interrupt Status Registers is being read, the event is held until after its register is cleared and then placed in the register.

register reflects the logic levels present on the data

The mnemonics for each of the bits in these registers and a brief description of their respective functions appears in Table 4. This tables also indicates how each of the interrupt bits is set.

NOTE: The INT bit in the Address 0 Register is a duplicate of the INT bit in the Interrupt Status 2 Register. It is only a status bit. It does not generate interrupts and thus does not have a corresponding enable bit.

The BO and BI interrupts enable the user to perform data transfer cycles. BO indicates that a data byte should be written to the Data Out Register. It is set by TACS · (SWNS + SGNS) · RFD. It is reset when the data byte is written, ATN is asserted, or the 8291A exits TACS. Data should never be written to the Data Out Register before BO is set. Similarly, BI is set when an input byte is accepted into the 8291A and reset when the microprocessor reads the Data In Register. BO and BI are also reset by pon (power-on local message) and by a read of the Interrupt

Status 1 Register. However, if it is so desired, data transfer cycles may be performed without reading the Interrupt Status 1 Register if all interrupts except for BO or BI are disabled; BO and BI will automatically reset after each byte is transferred.

If the 8291A is used in the interrupt mode, the INT and DREQ pins can be dedicated to data input and output interrupts respectively by enabling BI and DMAO, provided that no other interrupts are enabled. This eliminates the need to read the interrupt status registers if a byte is received or transmitted.

The ERR bit is set to indicate the bus error condition when the 8291A is an active talker and tries to send a byte to the GPIB, but there are no active listeners (e.g., all devices on the GPIB are in AIDS). The logical equivalent of (nba  $\cdot$  TACS  $\cdot$  DAC  $\cdot$  RFD) will set this bit.

The DEC bit is set whenever DCAS has occurred. The user must define a known state to which all device functions will return in DCAS. Typically this state will be a power-on state. However, the state of the device functions at DCAS is at the designer's discretion. It should be noted that DCAS has no effect on the interface functions which are returned to a known state by the IFC (interface clear) message or the pon local message.

The END interrupt bit may be used by the microprocessor to detect that a multi-byte transfer has been completed. The bit will be set when the 8291A is an active listener (LACS) and either EOS (provided the End on EOS Received feature is enabled in the Auxiliary Register A) or EOI is received. EOS will generate an interrupt when the byte in the Data In Register matches the byte in the EOS register. Otherwise the interrupt will be generated when a true input is detected on EOI.

The GET interrupt bit is used by the microprocessor to detect that DTAS has occurred. It is set by the 8291A when the GET message is received while it is addressed to listen. The TRIG output pin of the 8291A fires when the GET message is received. Thus, the basic operation of device trigger may be started without microprocessor software intervention.

The APT interrupt bit indicates to the processor that a secondary address is available in the CPT register for validation. This interrupt will only occur if Mode 3 addressing is in effect. (Refer to the section on addressing.) In Mode 2, secondary addresses will be recognized automatically on the 8291A. They will be ignored in Mode 1.

The CPT interrupt bit flags the occurrence of an undefined command and of all secondary commands following an undefined command. The Command Pass Through feature is enabled by the B0 bit of Auxiliary Register B. Any message not decoded by the 8291A (not included in the state diagrams in Appendix B) becomes an undefined command. Note that any addressed command is automatically ignored when the 8291A is not addressed.

Undefined commands are read by the CPU from the Command Pass Through register of the 8291A. This register reflects the logic levels present on the data lines at the time it is read. If the CPT feature is enabled, the 8291A will hold off the handshake until this register is read.

An especially useful feature of the 8291A is its ability to generate interrupts from state transitions in the interface functions. In particular, the lower 3 bits of the Interrupt Status 2 Register, if enabled by the corresponding enable bits, will cause an interrupt upon changes in the following states as defined in the IEEE 488 Standard.

Bit 0 ADSC change in LIDS or TIDS or MJMN Bit 1 REMC change in LOCS or REMS Bit 2 LLOC change in LWLS or RWLS

The upper 4 bits of the Interrupt Status 2 Register are available to the processor as status bits. Thus, if one of the bits 0–2 generates an interrupt indicating a state change has taken place, the corresponding status bit (bits 3–5 may be read to determine what the new state is. To determine the nature of a change in addressed status (bit 0) the Address Status Register is available to be read. The SPC interrupt (bit 3 in Interrupt Status 2) is set upon exit from SPAS if APRS.STRS.SPAS occurred which indicates that the GPIB controller has read the bus serial poll status byte after the 8291A requested service (asserted SRQ). The SPC interrupt occurs once after the controller reads the status byte if service was requested.

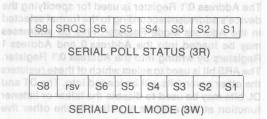

The controller may read the status byte later, and the byte will contain the last status the 8291A's CPU wrote to the Serial Poll Mode Register, but the SRQS bit will not be set and no interrupt will be generated. Finally, bit 7 monitors the state of the 8291A INT pin. Logically, it is an OR of all enabled interrupt status bits. One should note that bits 3–6 of the Interrupt Status 2 Register do not generate interrupts, but are available only to be read as status bits by the processor. Bit 7 in Interrupt Status 2 is duplicated in Address 0 Register, and the latter should be used when polling for interrupts to avoid losing one of the interrupts in Interrupt Status 2 Register.

Bits 4 and 5 (DMAI, DMAO) of the Interrupt Mask 2 Register are available to enable direct data transfers between memory and the GPIB; DMAI (DMA in) enables the DREQ (DMA request) pin of the 8291A to be asserted upon the occurrence of BI. Similarly, DMAO (DMA out) enables the DREQ pin to be asserted upon the occurrence of BO. One might note that the DREQ pin may be used as a second interrupt output pin, monitoring BI and/or BO and enabled by DMAI and DMAO. One should note that the DREQ pin is not affected by a read of the Interrupt Status 1 Register. It is reset whenever a byte is written to the Data Out Register or read from the Data In Register.

To ensure that an interrupt status bit will not be cleared without being read, and will not remain uncleared after being read, the 8291A implements a special interrupt handling procedure. When an enabled interrupt bit is set in either of the Interrupt Status Registers, the input of the registers are blocked until the set bit is read and reset by the microprocessor. Thus, potential problems arise when interrupt status changes while the register is being blocked. However, the 8291A stores all new interrupts in a temporary register and transfers them to the appropriate Interrupt Status Register after the interrupt has been reset. This transfer takes place only if the corresponding bits were read as zeroes.

### **Serial Poll Registers**

The Serial Poll Mode Register determines the status byte that the 8291A sends out on the GPIB data lines when it receives the SPE (Serial Poll Enable) message. Bit 6 of this register is reserved for the rsv (request service) local message. Setting this bit to 1 causes the 8291A to assert its SRQ line, indicating its need for attention from the controller-in-charge of the GPIB. The other bits of this register are available for sending status information over the GPIB. Sometime after the microprocessor initiates a request for service by setting bit 6, the controller of the GPIB sends the SPE message and then addresses the 8291A to talk. At this point, one byte of status is returned by the 8291A via the Serial Poll Mode Register. After the status byte is read by the controller, rsv is automatically cleared by the 8291A and an SPC interrupt is generated. The CPU may request service again by writing another byte to the Serial Poll Mode Register with the rsv bit set. If the controller performs a serial poll when the rsv bit is clear, the last status byte written will be read, but the SRQ line will not be driven by the 8291A and the SRQS bit will be clear in the status byte.

The Serial Poll Status Register is available for reading the status byte in the Serial Poll Mode Register. The processor may check the status of a request for service by polling bit 6 of this register, which corresponds to SRQS (Service Request State). When a Serial Poll is conducted and the controller-incharge reads the status byte, the SRQS bit is cleared. The  $\overline{\rm SRQ}$  line and the rsv bit are tied together.

by the microprocessor when Mode 3 is used. W

The Address Mode Register is used to select one of the five modes of addressing available on the 8291A. It determines the way in which the 8291A uses the information in the Address 0 and Address 1 Registers.

—In Mode 1, the contents of the Address 0 Register constitute the "Major" talker/listener address while the Address 1 Register represents the "Minor" talker/listener address. In applications where only one address is needed, the major talker/listener is used, and the minor talker/listener should be disabled. Loading an address via the Address 0/1 Register into Address Registers 0 and 1 enables the major and minor talker/listener functions respectively.

—In Mode 2 the 8291A recognizes two sequential address bytes: a primary followed by a secondary. Both address bytes must be received in order to enable the device to talk or listen. In this manner, Mode 2 addressing implements the extended talker and listener functions as defined in IEEE-488.

To use Mode 2 addressing the primary address must be loaded into the Address 0 Register, and the Secondary Address is placed in the Address 1 Register. With both primary and secondary addresses residing on chip, the 8291A can handle all addressing sequences without processor intervention.

—In Mode 3, the 8291A handles addressing just as it does in Mode 1, except that each Major or Minor primary address must be followed by a secondary address. All secondary addresses must be verified by the microprocessor when Mode 3 is used. When the 8291A is in TPAS or LPAS (talker/listener primary addressed state), and it does not recognize the byte on the DIO lines, an APT interrupt is generated (see section on Interrupt Registers) and the byte is available in the CPT (Command Pass-Through) Register. As part of its interrupt service routine, the microprocessor must read the CPT Register and write one of the following responses to the Auxiliary Mode Register:

- 1. 07H implies a non-valid secondary address
- 2. 0FH implies a valid secondary address

Setting the TO bit generates the local ton (talk-only) message and sets the 8291A to a talk-only mode. This mode allows the device to operate as a talker in an interface system without a controller.

Setting the LO bit generates the local lon (listenonly) message and sets the 8291A to a listen-only mode. This mode allows the device to operate as a listener in an interface system without a controller. The above bits may also be used by a controller-incharge to set itself up for remote command or data communication.

The mode of addressing implemented by the 8291A may be selected by writing one of the following bytes to the Address Mode Register.

#### Register Contents Mode

10000000	Enable talk only mode (ton)
01000000	Enable listen only mode (lon)
11000000	The 8291 may talk to itself
0000001	Mode 1, (Primary-Primary)
00000010	Mode 2 (Primary-Secondary)
00000011	Mode 3 (Primary/APT-Primary/APT)

The Address Status Register contains information used by the microprocessor to handle its own addressing. This information includes status bits that monitor the address state of each talker/ listener, "ton" and "lon" flags which indicate the talk and listen only states, and an EOI bit which, when set, signifies that the END message came with the last data byte. LPAS and TPAS indicate that the listener or talker primary address has been received. The microprocessor can use these bits when the secondary address is passed through to determine whether the 8291A is addressed to talk or listen. The LA (listener addressed) bit will be set when the 8291A is in LACS (Listener Active State) or in LADS (Listener Addressed State). Similarly, the TA (Talker Addressed bit) will be set to indicate TACS or TADS. but also to indicate SPAS (Serial Poll Active State). The MJMN bit is used to determine whether the information in the other bits applies to the Major or Minor talker/listener. It is set to "1" when the Minor talker/listener is addressed. It should be noted that only one talker/listener may be active at any one time. Thus, the MJMN bit will indicate which, if either, of the talker/listeners is addressed or active.

The Address 0/1 Register is used for specifying the device's addresses according to the format selected in the Address Mode Register. Five bit addresses may be loaded into the Address 0 and Address 1 Registers by writing into the Address 0/1 Register. The ARS bit is used to select which of these registers the other seven bits will be loaded into. The DT and DL bits may be used to disable the talker or listener function at the address signified by the other five

bits. When Mode 1 addressing is used and only one primary address is desired, *both* the talker and the listener should be disabled at the Minor address.

As an example of how the Address 0/1 Register might be used, consider an example where two primary addresses are needed in the device. The Major primary address will be selectable only as a talker and the Minor primary address will be selectable only as a listener. This configuration of the 8291A is formed by the following sequence of writes by the microprocessor.

Operation	CS	RD	WR	Data	RS2-RS0
1. Select addressing Mode 1	0	1	0	00000001	100
<ol><li>Load major address into Address 0 Register with listener function disabled.</li></ol>	0	1 <sub>e</sub>	0	001AAAAA	110
<ol> <li>Load minor address into Address 1 Register with talker function disabled.</li> </ol>	0	id di disi	-600	110BBBBB	ian <sup>110</sup> a

At this point, the addresses AAAAA and BBBBB are stored in the Address 0 and Address 1 Registers respectively, and are available to be read by the microprocessor. Thus, it is not necessary to store any address information elsewhere. Also, with the information stored in the Address 0 and Address 1 Registers, processor intervention is not required to recognize addressing by the controller. Only in Mode 3, where secondary addresses are passed through, must the processor intervene in the addressing sequence.

The Address 0 Register contains a copy of bit 7 of the Interrupt Status 2 Register (INT). This is to be used when polling for interrupts. Software should poll register 6 checking for INT (bit 7) to be set. When INT is set, the Interrupt Status Register should be read to determine which interrupt was received.

COMMAND PASS THROUGH (5R)

The Command Pass Through Register is used to transfer undefined 8-bit remote message codes from the GPIB to the microprocessor. When the CPT feature is enabled (bit B0 in Auxiliary Register B), any message not decoded by the 8291A becomes an undefined command. When Mode 3 addressing is used secondary addresses are also passed through

the CPT Register. In either case, the 8291A will holdoff the handshake until the microprocessor reads this register and issues the VSCMD auxiliary command.

The CPT and APT interrupts flag the availability of undefined commands and secondary addresses in the CPT Register. The details of these interrupts are explained in the section on Interrupt Registers.

An added feature of the 8291A is its ability to handle undefined secondary commands following undefined primaries. Thus, the number of available commands for future IEEE-488 definition is increased; one undefined primary command followed by a sequence of as many as 32 secondary commands can be processed. The IEEE-488 Standard does not permit users to define their own commands, but upgrades of the standard are thus provided for.

The recommended use of the 8291A's undefined command capabilities is for a controller-configured Parallel Poll. The PPC message is an undefined primary command typically followed by PPE, an undefined secondary command. For details on this procedure, refer to the section on Parallel Poll Protocol.

# **Auxiliary Mode Register**

CNT2 CNT1 CNT0 COM4 COM3 COM2 COM1 COM0
---

AUX MODE (5W)

CNT0-2:CONTROL BITS
COM0-4:COMMAND BITS

The Auxiliary Mode Register contains a three-bit control field and a five-bit command field. It is used for several purposes on the 8291A:

- 1. To load "hidden" auxiliary registers on the 8291A
- To issue commands from the microprocessor to the 8291A.
- To preset an internal counter used to generate T1, delay in the Source Handshake function, as defined in IEEE-488.

Table 5 summarizes how these tasks are performed with the Auxiliary Mode Register. Note that the three control bits determine how the five command bits are interpreted.

the CPT Register, in eith celds the 8291A will hold-

d foil10 ed dary com- Standard own com-	USP <sub>3</sub> P <sub>2</sub> P <sub>1</sub>	Enable/disable parallel poll either in response to remote messages (PPC followed by PPE or PPD) or as a local lpe message. (Enable if U = 0, disable if U = 1.)				

# AUXILIARY COMMANDS VIISOIGY BRAMMOO VISM

Auxiliary commands are executed by the 8291A whenever 0000CCCC is written into the Auxiliary Mode Register, where CCCC is the 4-bit command code.

0000—Immediate Execute pon: This command resets the 8291A to a power up state (local pon message as defined in IEEE-488).

The following conditions constitute the power up state:

- 1. All talkers and listeners are disabled.
- 2. No interrupt status bits are set.

The 8291A is designed to power up in certain states as specified in the IEEE-488 state diagrams. Thus, the following states are in effect in the power up state: SIDS, AIDS, TIDS, LIDS, NPRS, LOCS, and PPIS.

The "0000" pon is an immediate execute command (a pon pulse). It is also used to release the "initialize" state generated by either an external reset pulse or the "0010" Chip Reset command.

**0010**—Chip Reset (Initialize): This command has the same effect as a pulse applied to the Reset pin. (Refer to the section on Reset Procedure.)

0011 — Finish Handshake: This command finishes a handshake that was stopped because of a holdoff on RFD. (Refer to Auxiliary Register A.)

0100—Trigger: A "Group Execute Trigger" is forced by this command. It has the same effect as a GET command issued by the controller-in-charge of the GPIB, but does not cause a GET interrupt.

0101, 1101—Clear/Set rtl: These commands correspond to the local rtl message as defined by the IEEE-488. The 8291A will go into local mode when a Set rtl Auxiliary Command is received if local lockout is not in effect. The 8291A will exit local mode after receiving a Clear rtl Auxiliary Command if the 8291A is addressed to listen.

0110—Send EOI: The EOI line of the 8291A may be asserted with this command. The command causes EOI to go true with the next byte transmitted. The EOI line is then cleared upon completion of the handshake for that byte.

0111, 1111—Non Valid/Valid Secondary Address or Command (VSCMD): This command informs the 8291A that the secondary address received by the microprocessor was valid or invalid (0111 = invalid, 1111 = valid). If Mode 3 addressing is used, the processor must field each extended address and respond to it, or the GPIB will hang up. Note that the COM3 bit is the invalid/valid flag.

The valid (1111) command is also used to tell the 8291A to continue from the command-pass-through-state, or from RFD holdoff on GET, SDC or DCL.

1000—pon: This command puts the 8291A into the pon (power on) state and holds it there. It is similar to a Chip Reset except none of the Auxiliary Mode Registers are cleared. In this state, the 8291A does not participate in any bus activity. An Immediate Execute pon releases the 8291A from the pon state and permits the device to participate in the bus activity again.

0001, 1001—Parallel Poll Flag (local "ist" message): This command sets (1001) or clears (0001) the parallel poll flag. A "1" is sent over the assigned data line (PRR = Parallel Poll Response true) only if the parallel poll flag matches the sense bit from the Ipe local message (or indirectly from the PPE message). For a more complete description of the Parallel Poll features and procedures refer to the section on Parallel Poll Protocol.

## INTERNAL COUNTER

The internal counter determines the delay time allowed for the setting of data on the DIO lines. This delay time is defined as T<sub>1</sub> in IEEE-488 and appears in the Source Handshake state diagram between the

SDYS and STRS. As such, DAV is asserted  $T_1$  after the DIO lines are driven. Consequently,  $T_1$  is a major factor in determining the data transfer rate of the 8291A over the GPIB ( $T_1 = TWRDV2-TWRD15$ ).

When open-collector transceivers are used for connection to the GPIB,  $T_1$  is defined by IEEE-488 to be  $2\mu$ sec. By writing 0010DDDD into the Auxiliary Mode Register, the counter is preset to match a  $f_C$  MHz clock input, where DDDD is the binary representation of  $N_F$  [1 $\leq$ N<sub>F</sub> $\leq$ 8,  $N_F$ =(DDDD)<sub>2</sub>]. When  $N_F$  =  $f_C$ , a  $2\mu$ sec  $T_1$  delay will be generated before each DAV asserted.

$$T_{1(\mu sec)} = \frac{2N_F}{f_C} + t_{SYNC} , 1 \le N_F \le 8$$

 $t_{\scriptsize \text{SYNC}}$  is a synchronization error, greater than zero and smaller than the larger of T clock high and T clock low. (For a 50% duty cycle clock,  $t_{\scriptsize \text{SYNC}}$  is less than half the clock cycle).

If it is necessary that  $T_1$  be different from  $2\mu sec$ ,  $N_F$  may be set to a value other than  $f_C$ . In this manner, data transfer rates may be programmed for a given system. In small systems, for example, where transfer rates exceeding GPIB specifications are required, one may set  $N_F < f_C$  and decrease  $T_1$ .

When tri-state transceivers are used, IEEE-488 allows a higher transfer rate (lower  $T_1$ ). Use of the 8291A with such transceivers is enabled by setting  $B_2$  in Auxiliary Register B. In this case, setting  $N_F = f_C$  causes a  $T_1$  delay of  $2\mu$ sec to be generated for the first byte transmitted — all subsequent bytes will have a delay of 500 nsec.

$$T_1$$
(High Speed)  $\mu$ sec =  $\frac{N_F}{2f_C} + t_{SYNC}$ 

Thus, the shortest T<sub>1</sub> is achieved by setting  $N_F = 1$  using an 8 MHz clock with a 50% duty cycle clock ( $t_{SYNC} < 63$  nsec):

$$T_{1(HS)} = \frac{1}{2x8} + 0.063 = 125 \text{ nsec max.}$$

#### AUXILIARY REGISTER A set calls at opassem aid T

Auxiliary Register A is a "hidden" 5-bit register which is used to enable some of the 8291A features. Whenever a 100 A<sub>4</sub>A<sub>3</sub>A<sub>2</sub>A<sub>1</sub>A<sub>0</sub> byte is written into the

Auxiliary Register, it is loaded with the data  $A_4A_3A_2A_1A_0$ . Setting the respective bits to "1" enables the following features.

A<sub>0</sub>— RFD Holdoff on all Data: If the 8291A is listening, RFD will not be sent true until the "finish handshake" auxiliary command is issued by the microprocessor. The holdoff will be in effect for each data byte.

B .- Enable Undefined Command Pass Through:

A,—RFD Holdoff on End: This feature enables the holdoff on EOI or EOS (if enabled). However, no holdoff will be in effect on any other data bytes.

A<sub>2</sub>—End on EOS Received: Whenever the byte in the Data In Register matches the byte in the EOS Register, the END interrupt bit will be set in the Interrupt Status 1 Register.

A<sub>3</sub>—Output EOI on EOS Sent: Any occurrence of data in the Data Out Register matching the EOS Register causes the EOI line to be sent true along with the data.

A<sub>4</sub>—EOS Binary Compare: Setting this bit causes the EOS Register to function as a full 8-bit word. When it is not set, the EOS Register is a 7-bit word (for ASCII characters).

If A<sub>0</sub>=A<sub>1</sub>=1, a special "continuous Acceptor Handshake cycling" mode is enabled. This mode should be used only in a controller system configuration, where both the 8291A and the 8292 are used. It provides a continuous cycling through the Acceptor Handshake state diagram, requiring no local messages from the microprocessor; the rdy local message is automatically generated when in ANRS. As such, the 8291A Acceptor Handshake serves as the controller Acceptor Handshake. Thus, the controller cycles through the Acceptor Handshake without delaying the data transfer in progress. When the tcs local message is executed, the 8291A should be taken out of the "continuous AH cycling" mode, the GPIB will hang up in ANRS, and a BI interrupt will be generated to indicate that control may be taken. A simpler procedure may be used when a "tcs on end of block" is executed; the 8291A may stay in "continuous AH cycling". Upon the end of a block (EOI or EOS received), a holdoff is generated, the GPIB hangs up in ANRS, and control may be taken.

# AUXILIARY REGISTER B. H. Hereige A. YashixuA

Auxiliary Register B is a "hidden" 4-bit register which is used to enable some of the features of the 8291A. Whenever a 101 B<sub>4</sub>B<sub>3</sub>B<sub>2</sub>B<sub>1</sub>B<sub>0</sub> is written into the Auxiliary Mode Register, it is loaded with the data B<sub>4</sub>B<sub>3</sub>B<sub>2</sub>B<sub>1</sub>B<sub>0</sub>. Setting the respective bits to "1" enables the following features:

A.A.A.A.A. Setting the respective bits to "1"

B<sub>o</sub>—Enable Undefined Command Pass Through: This feature allows any commands not recognized by the 8291A to be handled in software. If enabled, this feature will cause the 8291A to holdoff the handshake when an undefined command is received. The microprocessor must then read the command from the Command Pass Through Register and send the VSCMD auxiliary command. Until the VSCMD command is sent, the handshake holdoff will be in effect.

B<sub>1</sub>—Send EOI in SPAS: This bit enables EOI to be sent with the status byte; EOI is sent true in Serial Poll Active State. Otherwise, EOI is sent false in SPAS.

 $B_2$ —Enable High Speed Data Transfer: This feature may be enabled when tri-state external transceivers are used. The data transfer rate is limited by  $T_1$  delay time generated in the Source Handshake function, which is defined according to the type of transceivers used. When the "High Speed" feature is enabled,  $T_1=2$  microseconds is generated for the first byte transmitted after each true to false transition of ATN. For all subsequent bytes,  $T_1=500$  nanoseconds. Refer to the Internal Counter section for an explanation of  $T_1$  duration as a function of  $B_2$  and of clock frequency.

**B**<sub>3</sub>—Enable Active Low Interrupt: Setting this bit causes the polarity of the INT pin to be reversed, providing an output signal compatible with Intel's MCS-48® Family. Interrupt registers are not affected by this bit.

Handshake state diagram, requiring no local mes-

B<sub>4</sub>—Enable RFD Holdoff on GET or DEC; Setting this bit causes RFD to be held false until the "VSCMD" auxiliary command is written after GET, SDC, and DCL commands. This allows the device to hold off the bus until it has completed a clear or trigger similar to an unrecognized command.

# PARALLEL POLL PROTOCOL SA SRTS bas SYOS

Writing a 011USP $_3$ P $_2$ P $_1$  into the Auxiliary Mode Register will enable (U=0) or disable (U=1) the 8291A for a parallel poll. When U=0, this command is the "lpe" (local poll enable) local message as defined in IEEE-488. The "S" bit is the sense in which the 8291A is enabled; only if the Parallel Poll Flag ("ist" local message) matches this bit will the Parallel Poll Response, PPR $_N$ , be sent true (Response= S + ist). The bits P $_3$ P $_2$ P $_1$  specify which of the eight data lines PPR $_N$  will be sent over. Thus, once the 8291A has been configured for Parallel Poll, whenever it senses both EOI and ATN true, it will automatically compare its PP flag with the sense bit and send PPR $_N$  true or false according to the comparison.

the DiO lines are driven. Consequently, T, is a major

If a PP2\* implementation is desired, the "Ipe" and "ist" local messages are all that are needed. Typically, the user will configure the 8291A for Parallel Poll immediately after initialization. During normal operation the microprocessor will set or clear the Parallel Poll Flag (ist) according to the device's need for service. Consequently the 8291A will be set up to give the proper response to IDY (EOI • ATN) without directly involving the microprocessor.

If a PP1\* implementation is desired, the undefined command features of the 8291A must be used. In PP1, the 8291A is indirectly configured for Parallel Poll by the active controller on the GPIB. The sequence at the 8291A being enabled or disabled remotely is as follows:

- The PPC message is received and is loaded into the Command Pass Through Register as an undefined command. A CPT Interrupt is sent to the microprocessor; the handshake is automatically held off.
- The microprocessor reads the CPT Register and sends VSCMD to the 8291A, releasing the handshake.

Tries = 4 0.063 = 125 nsec max.

3. Having received an undefined primary command, the 8291A is set up to receive an undefined secondary command (the PPE or PPD message). This message is also received into the CPT Register, the handshake is held off, and the CPT interrupt is generated.

NOTE: \*As defined in IEEE Standard 488. 001 a nevener W

4. The microprocessor reads the PPE or PPD message and writes the command into the Auxiliary Mode Register (bit 7 should be cleared first). Finally, the microprocessor sends VSCMD and the ed handshake is released. A) beau ensight asemble

# **End of Sequence (EOS) Register**

dan be configure REGISTER soughno ed nab

The EOS Register and its features offer an alternative to the "Send EOI" auxiliary command. A seven or eight bit byte (ASCII or binary) may be placed in the register to flag the end of a block or read. The type of EOS byte to be used is selected in Auxiliary Register bit A4.

If the 8291A is a listener, and the "End on EOS Received" is enabled with bit A2, then an END interrupt is generated in the Interrupt Status 1 Register whenever the byte in the Data-In Register matches the byte in the EOS Register.

If the 8291A is a talker, and the "Output EOI on EOS Sent" is enabled with bit A3, then the EOI line is sent true with the next byte whenever the contents of the Data Out Register match the EOS register.

#### Reset Procedure

The 8291A is reset to an initialization state either by a pulse applied to its Reset pin, or by a reset auxiliary command (02H written into the Auxiliary Command Register). The following conditions are caused by a reset pulse (or local reset command):

- 1. A "pon" local message as defined by IEEE-488 is held true until the initialization state is released.
- 2. The Interrupt Status Registers are cleared (not Interrupt Enable Registers).
- 3. Auxiliary Registers A and B are cleared.
- 4. The Serial Poll Mode Register is cleared.
- 5. The Parallel Poll Flag is cleared.
- 6. The EOI bit in the Address Status Register is
- 7. N<sub>F</sub> in the Internal Counter is set to 8 MHz. This setting causes the longest possible T1 delay to be generated in the Source Handshake (16 µsec for 1 MHz clock).

The initialization state is released by an "immediate execute pon" command (00H written into the Auxiliary Command Register). both detailed 3. The 8291A sends DAV true on the GPIB and pro-

The suggested initialization sequence is:

- 1. Apply a reset pulse or send the reset auxiliary Status Register should be read and the bnammon
- 2. Set the desired intial conditions by writing into the Interrupt Enable, Serial Poll Mode, Address Mode, Address 0/1, and EOS Registers. Auxiliary Registers A and B, and the internal counter should also be initialized.
- 3. Send the "immediate execute pon" auxiliary command to release the initialization state.
- 4. If a PP2 Parallel Poll implementation is to be used 8 the "lpe" local message may be sent, enabling the 8291A for a Parallel Poll Response on an assigned line. (Refer to the section on Parallel Poll Protocol.)

# Using DMA

The 8291A may be connected to the Intel® 8237 or 8257 DMA Controllers or the 8089 I/O Processor for DMA operation. The 8237 will be used to refer to any DMA controller. The DREQ pin of the 8291A requests a DMA byte transfer from the 8237. It is set by BO or BI flip flops, enabled by the DMAO and DMAI bits in the Interrupt Enable 2 Register. (After reading, the INT1 register BO and BI interrupts will be cleared but not BO and BI in DREQ equation.)

The DACK pin is driven by the 8237 in response to the DMA request. When DACK is true (active low) it sets CS = RS0 = RS1 = RS2 = 0 such that the RD and WR signals sent by the 8237 refer to the Data In and Data Out Registers. Also, the DMA request line is reset by DACK (RD + WR).

### DMA input sequence:

- 1. A data byte is accepted from the GPIB by the 8291A.
- 2. A BI interrupt is generated and DREQ is set.
- 3. DACK and RD are driven by the 8237, the contents of the Data In Register are transferred to the system bus, and DREQ is reset.
- 4. The 8291A sends RFD true on the GPIB and proceeds with the Acceptor Handshake protocol.

#### DMA output sequence:

1. A BO interrupt is generated (indicating that a byte 8. The rdy local message is sent. The rdy local message is sent. The rdy local message is sent.

- DACK and WR are driven by the 8237, a byte is transferred from the MCS bus into the Data Out Register, and DREQ is reset.
- 3. The 8291A sends DAV true on the GPIB and proceeds with the Source Handshake protocol.

It should be noted that each time the device is addressed (MTA + MLA + ton + Ion), the Address Status Register should be read, and the 8237 should be initialized accordingly. (Refer to the 8237 or 8257 Data Sheets.)

#### APPLICATION BRIEF

# System Configuration sibemail edit bae?

#### MICROPROCESSOR BUS CONNECTION

The 8291A is 8048/49, 8051, 8080/85, and 8086/88

compatible. The three address pins  $(RS_0, RS_1, RS_2)$  should be connected to the non-multiplexed address bus (for example:  $A_8$ ,  $A_9$ ,  $A_{10}$ ). In case of 8080, any address lines may be used. If the three lowest address bits are used  $(A_0, A_1, A_2)$ , then they must be demultiplexed first.

# **EXTERNAL TRANSCEIVERS CONNECTION**

The 8293 GPIB Transceiver interfaces the 8291A directly to the IEEE-488 bus. The 8291A and two 8293's can be configured as a talker/listener (see Figure 6) or with the 8292 as a talker/listener/controller (see Figure 7). Absolutely no active or passive external components are required to comply with the complete IEEE-488 electrical specification.

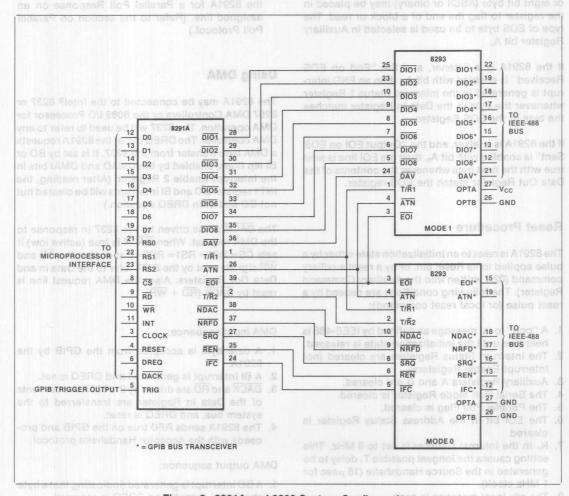

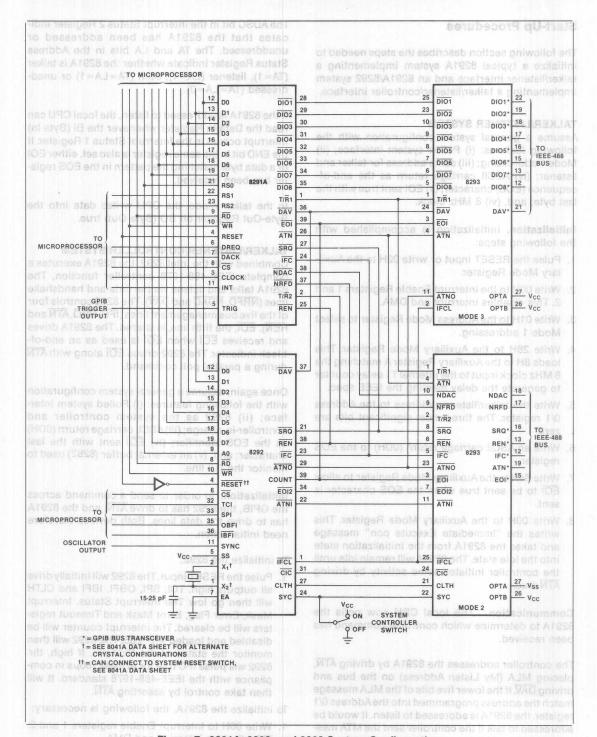

Figure 6. 8291A and 8293 System Configuration of 908 2207 (800) ybs and 8

AMC Prigure 7. 8291A, 8292, and 8293 System Configuration

1-269

# **Start-Up Procedures**

The following section describes the steps needed to initialize a typical 8291A system implementing a talker/listener interface and an 8291A/8292 system implementing a talker/listener/controller interface.

#### TALKER/LISTENER SYSTEM

Assume a general system configuration with the following features: (i) Polled system interface; (ii) Mode 1 addressing; (iii) same address for talker and listener; (iv) ASCII carriage return as the end-of-sequence (EOS) character; (v) EOI sent true with the last byte; and, (vi) 8 MHz clock.

**Initialization.** Initialization is accomplished with the following steps:

- Pulse the RESET input or write 02H to the Auxiliary Mode Register.
- Write 00H to the Interrupt Enable Registers 1 and 2. This disables interrupt and DMA.
- Write 01H to the Address Mode Register to select Mode 1 addressing.
- 4. Write 28H to the Auxiliary Mode Register. This loads 8H to the Auxiliary Register A matching the 8 MHz clock input to the internal T1 delay counter to generate the delay meeting the IEEE spec.
- Write the talker/listener address to the Address 0/1 register. The three most significant bits are zero.
- Write an ASCII carriage return (0DH) to the EOS register.
- 7. Write 84H to the Auxiliary Mode Register to allow EOI to be sent true when the EOS character is sent.
- 8. Write 00H to the Auxiliary Mode Register. This writes the "Immediate Execute pon" message and takes the 8291A from the initialization state into the idle state. The 8291A will remain idle until the controller initiates some activity by driving ATN true.

**Communication.** The local CPU now polls the 8291A to determine which controller command has been received.

The controller addresses the 8291A by driving ATN, placing MLA (My Listen Address) on the bus and driving DAV. If the lower five bits of the MLA message match the address programmed into the Address 0/1 register, the 8291A is addressed to listen. It would be addressed to talk if the controller sent the MTA message instead of MLA.

The ADSC bit in the Interrupt Status 2 Register indicates that the 8291A has been addressed or unaddressed. The TA and LA bits in the Address Status Register indicate whether the 8291A is talker (TA=1), listener (LA=1), both (TA=LA=1) or unaddressed (TA=LA=0).

If the 8291A is addressed to listen, the local CPU can read the Data-In Register whenever the BI (Byte In) interrupt occurs in the Interrupt Status 1 Register. If the END bit in the same register is also set, either EOI or a data byte matching the pattern in the EOS register has been received.

In the talker mode, the CPU writes data into the Byte-Out Register on BO (Byte Out) true.

#### TALKER/LISTENER/CONTROLLER SYSTEM

Combined with the Intel 8292, the 8291A executes a complete IEEE-488-1978 controller function, The 8291A talks and listens via the data and handshake lines (NRFD, NDAC and DAV). The 8292 controls four of the five bus management lines (IFC, SRQ, ATN and REN). EOI, the fifth line, is shared. The 8291A drives and receives EOI when EOI is used as an end-of-block indicator. The 8292 drives EOI along with ATN during a parallel poll command.

Once again, assume a general system configuration with the following features: (i) Polled system interface; (ii) 8292 as the system controller and controller-in-charge; (iii) ASCII carriage return (0DH) as the EOS identifier; (iv) EOI sent with the last character; and, (v) an external buffer (8282) used to monitor the TCI line.

Initialization. In order to send a command across the GPIB, the 8292 has to drive ATN, and the 8291A has to drive the data lines. Both devices therefore need initialization.

#### To initialize the 8292:

1. Pulse the RESET input. The 8292 will initially drive all outputs high. TCI, SPI, OBFI, IBFI and CLTH will then go low. The Interrupt Status, Interrupt Mask, Error Flag, Error Mask and Timeout registers will be cleared. The interrupt counter will be disabled and loaded with 255. The 8292 will then monitor the status of the SYC pin. If high, the 8292 will pulse IFC true for at least 100μs in compliance with the IEEE-488-1978 standard. It will then take control by asserting ATN.

To initialize the 8291A, the following is necessary:

ntroller sent the MTA mes
1. Write 00H to Interrupt Enable registers 1 and 2.

nothing find metay 2 8828 bns. This disables interrupt and DMA.

- With the 8292 as the controller-in-charge, it is impossible to address the 8292 via the GPIB. Therefore, the ton or lon modes of the 8291A must be used. To send comands, set the 8291A in the ton mode by writing 80H to the Address Mode Register.
- 3. Write 26H to the Auxiliary Mode Register to match the T1 data settling time to the 6 MHz clock input.
- Write an ASCII carriage return (0DH) to the EOS Register.
- 5. Write 84H to the Auxiliary Mode Register in order to enable "Output EOI on EOS sent" and thus send EOI with the last character.
- Write 00H—Immediate Execute pon—to the Auxiliary Mode Register to put the 8291A in the idle state.

   Aman Aman Aman and a state.

Communication. Since the 8291A is in the ton mode, a BO interrupt is generated as soon as the immediate Execute pon command is written. The CPU writes the command into the Data Out Register, and repeats it on BO becoming true for as many commands as necessary. ATN remains continuously

true unless the GTSB (Go To Standby) command is sent to the 8292.

ATN has to be false in order to send data rather than commands from the controller. To do this, the following steps are needed:

- 1. Enable the TCI interrupt if not already enabled.
- Wait for IBF (Input Buffer Full) in the 8292 Interrupt Status Register to be reset.
- Write the GTSB (F6H) command to the 8292 Command Field Register.
- 4. Read the 8282 and wait for TCl to be true.
- Write the ton (80H) and pon (00H) command to the 8291A Address Mode Register and Auxiliary Mode Registers respectively.
- 6. Wait for the BO interrupt to be set in the 8291A.
- 7. Write the data to the 8291A Data-Out Register.

Identically, the user could command the controller to listen rather than talk. To do that, write Ion (40H) instead of ton into the Address Mode Register. Then wait for BI rather than BO to go true. Read the data Register.

# **APPENDIX A**

## MODIFIED STATE DIAGRAMS

Figure A-1 presents the interface function state diagrams. It is derived from IEEE Std. state diagrams, with the following changes:

A. The 8291A supports the complete set of IEEE-488 interface functions except for the controller. These include: SH1, AH1, T5, TE5, L3, LE3, SR1, RL1, PP1, DC1, DT1, and C0.

B. Addressing modes included in T,L state diagrams.

Note that in Mode 3, MSA, OSA are generated only after secondary address validity check by the microprocessor (APT interrupt).

C. In these modified state diagrams, the IEEE-488-1978 convention of negative (low true) logic is followed. This should not be confused with the Intel pin- and signal-naming convention based on positive logic. Thus, while the state diagrams below carry low true logic, the signals described elsewhere in this data sheet are consistent with Intel notation and are based on positive logic.

-		Convention		
Level	Logic	IEEE-488	Intel	
0 (25)	METTER T	DAV	DAV	
1	F	DAV	DAV	
0	T	NDAC	NDAC	
1	F	NDAC	NDAC	
O VAO	T	NRFD	NRFD	
1	F	NRFD	NRFD	

Consider the condition when the Not-Ready-For-Data signal (pin 37) is active. Intel indicates this active low signal with the symbol  $\overline{\text{NRFD}}$  ( $V_{\text{OuT}} \leq V_{\text{OL}}$  for AH;  $V_{\text{IN}} \leq V_{\text{IL}}$  for SH). The IEEE-488-1978 Standard, in its state diagrams, indicates the active state of this signal (True condition) with NRFD.

D. All remote multiline messages decoded are conditioned by ACDS. The multiplication by ACDS is not drawn to simplify the diagrams.

E. The symbol

indicates:

- When event X occurs, the function returns to state S.
- 2. X overrides any other transition condition in the function.

Statement 2 simplifies the diagram, avoiding the explicit use of X to condition all transitions from S to other states.

# APPENDIX B

Table B-1. IEEE 488 Time Values

Time Value	Function (Applies to)	Description Description	Value
T1 /	SH	Settling Time for Multiline Messages	$\geq 2\mu s^2$
t <sub>2</sub>	LC,IC,SH,AH,T,L	Response to ATN	≤ 200ns
T <sub>3</sub>	AH	Interface Message Accept Time <sup>3</sup>	> 04
t4	T,TE,L,LE,C,CE	Response to IFC or REN False	< 100µs
t <sub>5</sub>	PP	Response to ATN+EOI	≤ 200ns
Т6	a C	Parallel Poll Execution Time	≥ 2 <i>µ</i> s
T <sub>7</sub>	( sawa )	Controller Delay to Allow Current Talker to see ATN Message	≥ 500 ns
T8	EGAL HD	Length of IFC or REN False	> 100µs
T <sub>9</sub>	C	Delay for EOI <sup>5</sup>	$\geq 1.5\mu s^6$

#### NOTES:

<sup>1</sup>Time values specified by a lower case t indicate the maximum time allowed to make a state transition. Time values specified by an upper case T indicate the minimum time that a function must remain in a state before exiting.

<sup>2</sup>If three-state drivers are used on the DIO, DAV, and EOI lines, T<sub>1</sub> may be:

- 1. ≥ 1100 ns
- 2. Or  $\geq$  700 ns if it is known that within the controller ATN is driven by a three-state driver.
- 3. Or ≥ 500ns for all subsequent bytes following the first sent after each false transition of ATN (the first byte must be sent in accordance with (1) or (2).
- Or ≥ 350ns for all subsequent bytes following the first sent after each false transition of ATN under conditions specified in Section 5.2.3 and warning note. See IEEE Standard 488.

<sup>3</sup>Time required for interface functions to accept, not necessarily respond to interface messages.

<sup>4</sup>Implementation dependent.

<sup>5</sup>Delay required for EOI, NDAC, and NRFD signal lines to indicate valid states.

6≥ 600 ns for three-state drivers.

FUNCTIONAL DESCRIPTION

#### **FUNCTIONAL DESCRIPTION**

The 8292 is an Intel 8041A which has been programmed as a GPIB Controller interface element. It is used with the 8291 GPIB Talker/Listener and two 8293 GPIB Transceivers to form a complete IEEE-488 Bus Interface for a microprocessor. The electrical interface is performed by the transceivers, data transfer is done by the talker/listener, and control of the bus is done by the 8292. Figure 3 is a typical controller interface using Intel's GPIB peripherals.

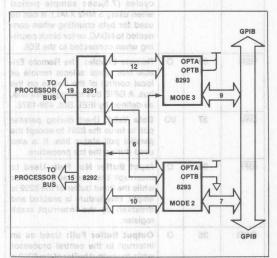

Figure 3. Talker/Listener/Controller Configuration

The internal RAM in the 8041A is used as a special purpose register bank for the 8292. Most of these registers (except for the interrupt flag) can be accessed through commands to the 8292. Table 2 identifies the registers used by the 8292 and how they are accessed.

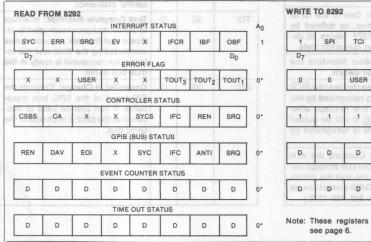

#### Interrupt Status Register

SYC	ERR	SRQ	EV	X	IFCR	IBF	OBF
-----	-----	-----	----	---	------	-----	-----

The 8292 can be configured to interrupt the microprocessor on one of several conditions. Upon receipt of the interrupt the microprocessor must read the 8292 interrupt status register to determine which event caused the interrupt, and then the appropriate subroutine can be performed. The interrupt status register is read with  $A_0$  high. With the exception of OBF and IBF, these interrupts are enabled or disabled by the SPI interrupt mask, OBF and IBF have their own bits in the interrupt mask (OBFI and  $\overline{\rm IBFI}$ ).

- OBF Output Buffer Full. A byte is waiting to be read by the microprocessor. This flag is cleared when the output data bus buffer is read.
- IBF Input Buffer Full. The byte previously written by the microprocessor has not been read yet by the 8292. If another byte is written to the 8292 before this flag clears, data will be lost. IBF is cleared when the 8292 reads the data byte.
- IFCR Interface Clear Received. The GPIB system controller has set IFC. The 8292 has become idle and is no longer in charge of the bus. The flag is cleared when the IACK command is issued.
- EV Event Counter Interrupt. The requested number of blocks or data bytes has been transferred. The EV interrupt flag is cleared by the IACK command.
- SRQ Service Request. Notifies the 8292 that a service request (SRQ) message has been received. It is cleared by the IACK command.
- ERR Error occurred. The type of error can be determined by reading the error status register. This interrupt flag is cleared by the IACK command.
- SYC System Controller Switch Change. Notifies the processor that the state of the system controller switch has changed. The actual state is contained in the GPIB Status Register. This flag is cleared by the IACK command.

#### Table 2. 8292 Registers

D	D	DO	D	D	D	D	D	0

Note: These registers are accessed by a special utility command, see page 6.

1 | SPI | TCI | SYC | OBFI | IBFI | 0 | SRQ

The Interrupt Mask Register is used to enable features and to mask the SPI and TCI interrupts. The flags in the Interrupt Status Register will be active even when masked out. The Interrupt Mask Register is written when  $A_0$  is low and reset by the RINM command. When the register is read,  $D_1$  and  $D_7$  are undefined. An intertupt is enabled by setting the corresponding register bit.

SRQ Enable interrupts on SRQ received to anabecome

IBFI Enable interrupts on input buffer empty.

OBFI Enable interrupts on output buffer full.

SYC Enable interrupts on a change in the system controller switch.

TCI Enable interrupts on the task completed.

SPI Enable interrupts on special events.

NOTE: The event counter is enabled by the GSEC command, the error interrupt is enabled by the error mask register, and IFC cannot be masked (it will always cause an interrupt).

#### Controller Status Register

CSBS	CAT	25 <b>(x</b> co u	(TX/8	SYCS	egFCd	REN	SRQ
D <sub>7</sub>	10.0 Ehr	by state	ssiand	All Bills	to tellor	moo en	D <sub>0</sub>

The Controller Status Register is used to determine the status of the controller function. This register is accessed by the RCST command.

SRQ Service Request line active (CSRS).

REN Sending Remote Enable.

IFC Sending or receiving interface clear.

SYCS System Controller Switch Status (SACS).

CA Controller Active (CACS + CAWS + CSWS).

CSBS Controller Stand-by State (CSBS, CA) = (0,0) — Controller Idle

#### will be generated by the 8292. The 8292 will respond to GPIB Bus Status Register: The Bus Status Register

REN	DAV	EOI	X	SYC	IFC	ATNI	SRQ
				time of	OF -		

This register contains GPIB bus status information. It can be used by the microprocessor to monitor and manage the bus. The GPIB Bus Register can be read using the RBST command.

Each of these status bits reflect the current status of the corresponding pin on the 8292.

SRQ Service Request 3 1980 and tellettage materia

**REN** Remote Enable

D<sub>7</sub> D<sub>6</sub> D<sub>5</sub> D<sub>4</sub> D<sub>3</sub> D<sub>2</sub> D<sub>1</sub> D<sub>0</sub>

The Event Counter Register contains the initial value for the event counter. The counter can count pulses on pin 39 of the 8292 (COUNT). It can be connected to EOI or NDAC to count blocks or bytes respectively during standby state. A count of zero equals 256. This register cannot be read, and is written using the WEVC command.

#### Event Counter Status Register bellioses bolled

20201 10	COURS DAY 1	A SEEKES	10/1 2/03	CHILIT	2013 111	White A	-
07	D <sub>6</sub>	D <sub>5</sub>	D <sub>4</sub>	D3	2280	D <sub>1</sub>	D0

This register contains the current value in the event counter. The event counter counts back from the initial value stored in the Event Counter Register to zero and then generates an Event Counter Interrupt. This register cannot be written and can be read using a REVC command.

#### **Time Out Register**

					north charles	SEL MEN	THE PARTY LAND
D <sub>7</sub>	D <sub>6</sub>	D <sub>5</sub>	D <sub>4</sub>	D <sub>3</sub>	D <sub>2</sub>	D <sub>1</sub>	D <sub>0</sub>

The Time Out Register is used to store the time used for the time out error function. See the individual timeouts (TOUT1, 2, 3) to determine the units of this counter. This Time Out Register cannot be read, and it is written with the WTOUT command.

#### Time Out Status Register 201 814T .1618190FL/88M 10113

		March Co.	1.1111111111111111111111111111111111111	2221125	THUS WITH	I THE PARTY OF	The second
D <sub>7</sub>	D <sub>6</sub>	D <sub>5</sub>	D <sub>4</sub>	D <sub>3</sub>	D <sub>2</sub>	D <sub>1</sub>	D <sub>0</sub>

This register contains the current value in the time out counter. The time out counter decrements from the original value stored in the Time Out Register. When zero is reached, the appropriate error interrupt is generated. If the register is read while none of the time out functions are active, the register will contain the last value reached the last time a function was active. The Time Out Status Register cannot be written, and it is read with the RTOUT command.

#### Error Flag Register, villity and al viccesso bridges and

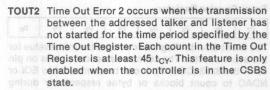

X	×	USER	X	×	TOUT <sub>3</sub>	TOUT <sub>2</sub>	TOUT
---	---	------	---	---	-------------------	-------------------	------

Four errors are flagged by the 8292 with a bit in the Error Flag Register. Each of these errors can be masked by the Error Mask Register. The Error Flag Register cannot be written, and it is read by the IACK command when the error flag in the Interrupt Status Register is set.

TOUT1 Time Out Error 1 occurs when the current controller has not stopped sending ATN after receiving the TCT message for the time period specified by the Time Out Register. Each count in the Time Out Register is at least 1800 toy.

After flagging the error, the 8292 will remain in a loop trying to take control until the current controller stops sending ATN or a new command is written by the microprocessor. If a new command is written, the 8292 will return to the loop after executing it.

# TOUT3 Time Out Error 3 occurs when the handshake signals are stuck and the 8292 is not succeeding in taking control synchronously for the time period specified by the Time Out Register. Each count in the Time Out Register is at least 1800 t<sub>CY</sub>. The 8292 will continue checking ATNI until it becomes true or a new command is received. After performing the new command, the 8292 will return to the ATNI checking loop.

USER User error occurs when request to assert IFC or REN was received and the 8292 was not the system controller.

#### **Error Mask Register**

0	0	USER	0	0	TOUT <sub>3</sub>	TOUT <sub>2</sub>	TOUT-

The Error Mask Register is used to mask the interrupt from a particular type of error. Each type of error interrupt is enabled by setting the corresponding bit in the Error Mask Register. This register can be read with the RERM command and written with  $A_0$  low.

#### **Command Register**

	1	1	1	OP	C	С	C	C
--	---	---	---	----	---	---	---	---

Commands are performed by the 8292 whenever a byte is written with  $A_0$  high. There are two categories of commands distinguished by the OP bit (bit 4). The first category is the operation command (OP=1). These commands initiate some action on the interface bus. The second category is the utility commands (OP=0). These commands are used to aid the communication between the processor and the 8292.

#### OPERATION COMMANDS

Operation commands initiate some action on the GPIB interface bus. It is using these commands that the control functions such as polling, taking and passing control, and system controller functions are performed. A TCI interrupt is generated upon successful completion of each of these functions.

#### F0 — SPCNI — Stop Counter Interrupts

This command disables the internal counter interrupt so that the 8292 will stop interrupting the master on event counter underflows. However, the counter will continue counting and its contents can still be used.

#### F1 - GIDL - Go To Idle

This command is used during the transfer of control procedure while transferring control to another controller. The 8292 will respond to this command only if it is in the active state. ATNO will go high, and CIC will be high so that this 8292 will no longer be driving the ATN line on the GPIB interface bus.

#### F2 - RST - Reset 9 entry disease but woll at A nadw

This command has the same effect as asserting the external reset on the 8292. For details, refer to the reset procedure described later.

#### F3 - RSTI - Reset Interrupts

This command resets any pending interrupts and clears the error flags. The 8292 will not return to any loop it was in (such as from the time out interrupts).

#### F4 - GSEC - Go To Standby, Enable Counting

The function causes ATNO to go high and the counter will be enabled. If the 8292 was not the active controller, this command will exit immediately. If the 8292 is the active controller, the counter will be loaded with the value stored in the Event Counter Register, and the internal interrupt will be enabled so that when the counter reaches zero, the SPI interrupt will be generated. SPI will be generated every 256 counts thereafter until the controller exits the standby state or the SPCNI command is written. An initial count of 256 (zero in the Event Counter Register) will be used if the WEVC command is not executed. If the data transmission does not start, a TOUT2 error will be generated.

#### F5 - EXPP - Execute Parallel Poll

This command initiates a parallel poll by asserting ATN and EOI (IDY message) true. The 8291 should be previously configured as a listener. Upon detection of DAV true, the 8291 enters ACDS and latches the parallel poll response (PPR) byte into its data in register. The master will be interrupted by the 8291 Bl interrupt when the PPR byte is available. No interrupts except the IBFI will be generated by the 8292. The 8292 will respond to this command only when it is the active controller.

#### F6 — GTSB — Go To Standby

If the 8292 is the active controller,  $\overline{\text{ATNO}}$  will go high then TCI will be generated. If the data transmission does not start, a TOUT2 error will be generated.

#### F7 — SLOC — Set Local Mode minos Tedal ent phiate

If the 8292 is the system controller, then REN will be asserted false for at least 100  $\mu sec.$  If it is not the system controller, the User Error bit will be set in the Error Flag Register.

#### F8 - SREM - Set Interface To Remote Control

This command will set REN true if this 8292 is the system controller. If not, the User Error bit will be set in the Error Flag Register.

This command will cause IFC to be asserted true for at least 100  $\mu$ sec if this 8292 is the system controller. If it is in CIDS, it will take control over the bus (see the TCNTR command).

#### FA - TCNTR - Take Control has used bluods 192 en

The transfer of control procedure is coordinated by the master with the 8291 and 8292. When the master receives a TCT message from the 8291, it should issue the TCNTR command to the 8292. The following events occur to take control:

- 1. The 8292 checks to see if it is in CIDS, and if not, it exits.
- Then ATNI is checked until it becomes high. If the current controller does not release ATN for the time specified by the Time Out Register, then a TOUT1 error is generated. The 8292 will return to this loop after an error or any command except the RST and RSTI commands.
- 3. After the current controller releases ATN, the 8292 will assert ATNO and CIC low.
- Finally, the TCI interrupt is generated to inform the master that it is in control of the bus.

#### FC — TCASY — Take Control Asynchronously

TCAS transfers the 8292 from CSBS to CACS independent of the handshake lines. If a bus hangup is detected (by an error flag), this command will force the 8292 to take control (asserting ATN) even if the AH function is not in ANRS (Acceptor Not Ready State). This command should be used very carefully since it may cause the loss of a data byte. Normally, control should be taken synchronously. After checking the controller function for being in the CSBS (else it will exit immediately), ATNO will go low, and a TCI interrupt will be generated.

#### FD — TCSY — Take Control Synchronously

There are two different procedures used to transfer the 8292 from CSBS to CACS depending on the state of the 8291 in the system. If the 8291 is in "continuous AH cycling" mode (Aux. Reg. A0 = A1 = 1), then the following procedure should be followed:

- The master microprocessor stops the continuous AH cycling mode in the 8291;
- 2. The master reads the 8291 Interrupt Status 1 Register:
- If the END bit is set, the master sends the TCSY command to the 8292;
- 4. If the END bit was not set, the master reads the 8291 Data In Register and then waits for another BI interrupt from the 8291. When it occurs, the master sends the 8292 the TCSY command.

If the 8291 is not in AH cycling mode, then the master just waits for a BI interrupt and then sends the TCSY command. After the TCSY command has been issued, the 8292 checks for CSBS. If CSBS, then it exits the routine. Otherwise, it then checks the DAV bit in the GPIB status. When DAV becomes false, the 8292 will

wait for at least 1.5  $\mu$ sec. (T10) and then  $\overline{\text{ATNO}}$  will go low. If DAV does not go low, a TOUT3 error will be generated.

#### FE — STCNI — Start Counter Interrupts

This command enables the internal counter interrupt. The counter is enabled by the GSEC command.

## UTILITY COMMANDS The between at 1900 and

All these commands are either Read or Write to registers in the 8292. Upon completion of Read commands, the TCI (Task Completed Interrupt) will be generated. Note that writing to the Error Mask Register and the Interrupt Mask Register are done directly.

#### E1 — WTOUT — Write To Time Out Register

The byte written to the data bus buffer (with  $A_0\!=\!0$ ) following this command will determine the time used for the time out function. Since this function is implemented in software, this will not be an accurate time measurement. This feature is enable or disable by the Error Mask Register. No interrupts except for the  $\overline{\text{IBFI}}$  will be generated upon completion.

#### E2 — WEVC — Write To Event Counter

The byte written to the data bus buffer (with  $A_0\!=\!0$ ) following this command will be loaded into the Event Counter Register and the Event Counter Status for byte counting or EOI counting. Only  $\overline{\text{IBFI}}$  will indicate completion of this command.

#### E3 - REVC - Read Event Counter Status

This command transfers the contents of the Event Counter into the data bus buffer. A TCI is generated when the data is available in the data bus buffer.

#### E4 — RERF — Read Error Flag Register

This command transfers the contents of the Error Flag Register into the data bus buffer. A TCI is generated when the data is available.

#### E5 - RINM - Read Interrupt Mask Register

This command transfers the contents of the Interrupt Mask Register into the data bus buffer. This register is available to the processor so that it does not need to store this information elsewhere. A TCI is generated when the data is available in the data bus buffer.

#### E6 — RCST — Read Controller Status Register

This command transfers the contents of the Controller Status Register into the data bus buffer and a TCI interrupt is generated.

#### E7 — RBST — Read GPIB Bus Status Register

This command transfers the contents of the GPIB Bus Status Register into the data bus buffer, and a TCI interrupt is generated when the data is available.

1-285 AFN-00741D

#### E9 — RTOUT — Read Time Out Status Register

This command transfers the contents of the Time Out Status Register into the data bus buffer, and a TCI interrupt is generated when the data is available.

#### EA — RERM — Read Error Mask Register

This command transfers the contents of the Error Mask Register to the data bus buffer so that the processor does not need to store this information elsewhere. A TCI interrupt is generated when the data is available.

#### Interrupt Acknowledge antia era abnammoo easiti IA

SYC	ERR	SRQ	EV	bete	IFCR	es 7)	1
D <sub>7</sub>	tereig	971, 718s	vi 1011	1 8/11	of Built	w tad	Do

Each named bit in an Interrupt Acknowledge (IACK) corresponds to a flag in the Interrupt Status Register. When the 8292 receives this command, it will clear the SPI and the corresponding bits in the Interrupt Status Register. If not all the bits were cleared, then the SPI will be set true again. If the error flag is not acknowledged by the IACK command, then the Error Flag Register will be transferred to the data bus buffer, and a TCI will be generated.

NOTE: XXXX1X11 is an undefined operation or utility command, so no conflict exists between the IACK operation and utility commands.

## SYSTEM OPERATION 103 TO DIVINUO

#### 8292 To Master Processor Interface

Communication between the 8292 and the Master Processor can be either interrupt based communication or based upon polling the interrupt status register in predetermined intervals.

#### Interrupt Based Communication | 1998 - 1998 - 1998

Four different interrupts are available from the 8292:

OBFI Output Buffer Full Interrupt

IBFI Input Buffer Not Full Interrupt

TCI Task Completed Interrupt | bask - MAIR - 88

SPI at Special Interrupt and analyment basemon aidT

Each of the interrupts is enabled or disabled by a bit in the interrupt mask register. Since OBFI and IBFI are directly connected to the OBF and IBF flags, the master can write a new command to the input data bus buffer as soon as the previous command has been read.

The TCI interrupt is useful when the master is sending commands to the 8292. The pending TCI will be cleared with each new command written to the 8292. Commands sent to the 8292 can be divided into two major groups:

- Commands that require response back from the 8292 to the master, e.g., reading register.
- Commands that initiate some action or enable features but do not require response back from the 8292, e.g., enable data bus buffer interrupts.

With the first group, the TCI interrupt will be used to indicate that the required response is ready in the data bus buffer and the master may continue and read it. With the second group, the interrupt will be used to indicate completion of the required task, so that the master may send new commands.

The SPI should be used when immediate information or special events is required (see the Interrupt Status Register).

#### "Polling Status" Based Communication of RTAGT ent

When interrupt based communication is not desired, all interrupts can be masked by the interrupt mask register. The communication with the 8292 is based upon sequential poll of the interrupt status register. By testing the OBF and IBF flags, the data bus buffer status is determined while special events are determined by testing the other bits.

#### Receiving IFC

The IFC pulse defined by the IEEE-488 standard is at least 100  $\mu sec.$  In this time, all operation on the bus should be aborted. Most important, the current controller (the one that is in charge at that time) should stop sending ATN or EOI. Thus, IFC must externally gate  $\overline{\text{CIC}}$  (controller in charge) and  $\overline{\text{ATNO}}$  to ensure that this occurs.

## Reset and Power Up Procedure

After the 8292 has been reset either by the external reset pin, the device being powered on, or a RST command, the following sequential events will take place:

- All outputs to the GPIB interface will go high (SRQ, ATNI, IFC, SYC, CLTH, ATNO, CIC, TCI, SPI, EOI, OBFI, IBFI, DAV, REV).
- The four interrupt outputs (TCI, SPI, OBFI, IBFI) and CLTH output will go low.
- 3. The following registers will be cleared:

Interrupt Status as upsoon a hareful own are ered T

8292 from CSBS to CACS depending skak trunners.

8291 in the system; if the 8291 is in 1939 grant of the g

Time Out

Event Counter (= 256), Counter is disabled.

- 4. If the 8292 is the system controller, an ABORT command will be executed, the 8292 will become the controller in charge, and it will enter the CACS state.
- If it is not the system controller, it will remain in

#### System Configuration next both netalger of stack

The 8291 and 8292 must be interfaced to an IEEE-488 bus meeting a variety of specifications including drive capability and loading characteristics. To interface the 8291 and the 8292 without the 8293's, several external gates are required, using a configuration similar to that used in Figure 5.

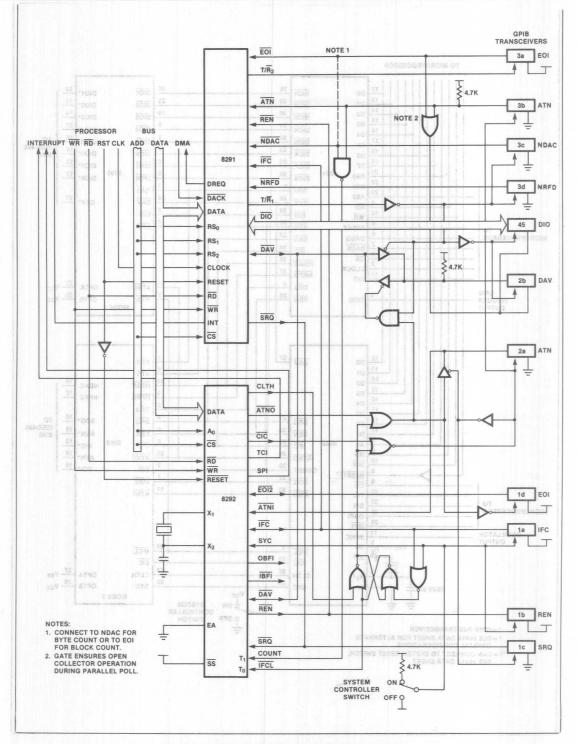

Figure 4. 8291 and 8292 System Configuration

#### 8293 GPIB TRANSCEIVER

- Nine Open-collector or Three-state
   Line Drivers
- 48 mA Sink Current Capability on Each Line Driver
- Nine Schmitt-type Line Receivers
- High Capacitance Load Drive Capability
- Single 5V Power Supply
- 28-Pin Package
- Low Power HMOS Design On-Chip IEEE-

- On-chip Decoder for Mode
   Configuration
- Power Up/Power Down Protection to Prevent Disrupting the IEEE Bus
- Connects with the 8291A and 8292 to Form an IEEE Standard 488 Interface Talker/Listener/Controller with no Additional Components
- Only Two 8293's Required per GPIB Interface
- On-Chip IEEE-488 Bus Terminations

The Intel® 8293 GPIB Transceiver is a high-current, non-inverting buffer chip designed to interface the 8291A GPIB Talker/Listener, or the 8291A/8292 GPIB Talker/Listener/Controller combination, to the IEEE Standard 488-1978 Instrumentation Interface Bus. Each GPIB interface would contain two 8293 Bus Transceivers. In addition, the 8293 can also be used as a general-purpose bus driver.

<sup>\*</sup>Note: These pins are the IEEE-488 bus non-inverting driver/receivers. They include all the bus terminations required by the Standard and may be connected directly to the GPIB bus connector.

#### GENERAL DESCRIPTION (beauthred) notice of

The 8293 is a bidirectional transceiver. It was designed to interface the Intel 8291A GPIB Talker/Listener and the Intel® 8292 GPIB Controller to the IEEE Standard 488-1978 Instrumentation Bus (also referred to as the GPIB). The Intel GPIB Transceiver meets or exceeds all of the electrical specifications defined in the IEEE Standard 488-1978, Section 3.3-3.5, including the bus termination specifications.

The 8293 can be hardware programmed to one of four modes of operation. These modes allow the 8293 to be configured to support both a Talker/Listener/Controller environment and a Talker/Listener environment. In addition, the 8293 can be used as a general-purpose, three-state (push-pull) or open-collector bus transceiver with nine receiver/drivers. Two modes each are used to support a Talker/Listener (see Figure 3) and a Talker/Listener/Controller environment (see Figure 4). Mode 1 is used in general-purpose environments.

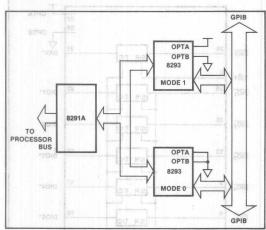

Figure 3. Talker/Listener Configuration

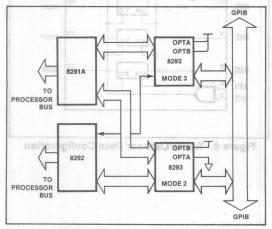

Figure 4. Talker/Listener/Controller Configuration

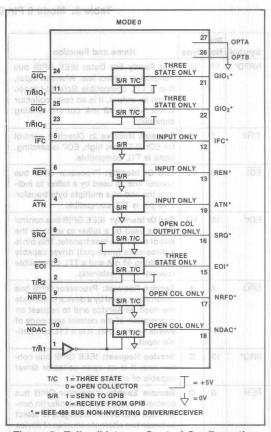

Figure 5. Talker/Listener Control Configuration

Table 3. Mode 0 Pin Description

Symbol	Pin No.	Туре	Name and Function			
T/R1	tnoo	TTI s	Transmit Receive 1 Direction control for NDAC and NRFD. If T/R1 is high, ther NDAC* and NRFD* are receiving. Input is TTL compatible.			
NDAC aud 919 of relic	10	I/O 88900 8 40	Not Data Accepted: Processor GPIE bus handshake control line; used to indicate the condition of acceptance of data by device(s). It is TTL compatible.			
NDAC*	18	18 I/O Not Data Accepted: IEEE GPIE handshake control line. When an it is a TTL compatible Schmitt-it When an output, it is an open-coll driver with 48 mA sinking capabili				
NRFD	9	I/O	Not Ready For Data: Processor GPIE handshake control line; used to indicate the condition of readiness of device(s to accept data. This pin is TTL compatible.			

Symbol	Pin No.	Туре	Name and Function				
NRFD* 17 1/O		1/0	Not Ready For Data: IEEE GPIB bus handshake control line. When an input, it is a TTL compatible Schmitt-trigger. When an output, it is an open-collector driver with a 48 mA current sinking capability.				
T/R2	2	Y <b>1</b> 380	<b>Transmit Receive 2:</b> Direction contro for EOI. If T/R2 is high, EOI* is sending Input is TTL compatible.				
EOI	3	1/0	End Or Identify: Processor GPIB to control line; is used by a talker to in cate the end of a multiple byte transf This pin is TTL compatible.				
EOI*	15	1/0	End Or Identify: IEEE GPIB bus contro line; is used by a talker to indicate the end of a multiple byte transfer. This pin is a three-state (push-pull) driver capable of sinking 48 mA and a TTL compatible receiver with hysteresis.				
SRQ	8	Y.180	Service Request: Processor GPIB bus control line; used by a device to indicate the need for service and to request an interruption of the current sequence of events on the GPIB. It is a TTL compatible input.				
SRQ*	16	0					
REN	6	esvisi noo l	Remote Enable: Processor GPIB bus control line; used by a controller (in con- junction with other messages) to select between two alternate sources of device programming data (remote or local con- trol). This output is TTL compatible.				
REN*	13	I Igno	Remote Enable: IEEE GPIB bus controlline. This input is a TTL compatible Schmitt-trigger.				
ATN  //  //  //  //  //  //  //  //  //	4 not	0	Attention: Processor GPIB bus control line; used by the 8291 to determine how data on the DIO signal lines are to be interpreted. This is a TTL compatible output.				
ATN*	19	904 s 619 si	Attention: IEEE GPIB bus control line this input is a TTL compatible Schmittrigger.				
IFC OF DE BONS AND ADDRESS AND		0	Interface Clear: Processor GPIB bus control line; used by a controller to place the interface system into a known quiescent state. It is a TTL compatible output.

The Intel® 8253 is a programmable counter/timer chip designed for use as an Intel microcomputer peripheral. It uses nMOS technology with a single +5V supply and is packaged in a 24-pin plastic DIP.

It is organized as 3 independent 16-bit counters, each with a count rate of up to 2 MHz. All modes of operation are software programmable.

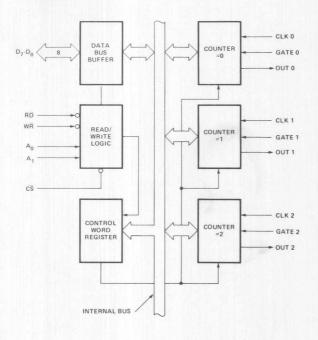

Figure 1. Block Diagram

Figure 2. Pin Configuration

#### **FUNCTIONAL DESCRIPTION**

#### General

The 8253 is a programmable interval timer/counter specifically designed for use with the Intel™ Microcomputer systems. Its function is that of a general purpose, multi-timing element that can be treated as an array of I/O ports in the system software.

The 8253 solves one of the most common problems in any microcomputer system, the generation of accurate time delays under software control. Instead of setting up timing loops in systems software, the programmer configures the 8253 to match his requirements, initializes one of the counters of the 8253 with the desired quantity, then upon command the 8253 will count out the delay and interrupt the CPU when it has completed its tasks. It is easy to see that the software overhead is minimal and that multiple delays can easily be maintained by assignment of priority

Other counter/timer functions that are non-delay in nature but also common to most microcomputers can be implemented with the 8253.

#### **Data Bus Buffer**

This 3-state, bi-directional, 8-bit buffer is used to interface the 8253 to the system data bus. Data is transmitted or received by the buffer upon execution of INput or OUTput CPU instructions. The Data Bus Buffer has three basic functions.

- 1. Programming the MODES of the 8253.
- 2. Loading the count registers.
- 3. Reading the count values.

#### Read/Write Logic

The Read/Write Logic accepts inputs from the system bus and in turn generates control signals for overall device operation. It is enabled or disabled by CS so that no operation can occur to change the function unless the device has been selected by the system logic.

#### RD (Read)

A "low" on this input informs the 8253 that the CPU is inputting data in the form of a counters value.

#### WR (Write)

A "low" on this input informs the 8253 that the CPU is outputting data in the form of mode information or loading

#### A0. A1

These inputs are normally connected to the address bus. Their function is to select one of the three counters to be operated on and to address the control word register for mode selection. CS (Chip Select)

A "low" on this input enables the 8253. No reading or writing will occur unless the device is selected. The CS input has no effect upon the actual operation of the

0	1	1	X	X	No-Operation 3-State

#### **Control Word Register**

The Control Word Register is selected when A0, A1 are 11. It then accepts information from the data bus buffer and stores it in a register. The information stored in this register controls the operational MODE of each counter, selection of binary or BCD counting and the loading of each count register.

The Control Word Register can only be written into; no read operation of its contents is available.

#### Counter #0, Counter #1, Counter #2

These three functional blocks are identical in operation so only a single Counter will be described. Each Counter consists of a single, 16-bit, pre-settable, DOWN counter. The counter can operate in either binary or BCD and its input, gate and output are configured by the selection of MODES stored in the Control Word Register.

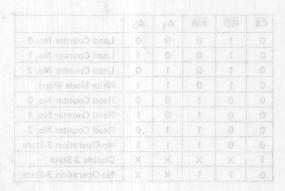

The counters are fully independent and each can have separate Mode configuration and counting operation, binary or BCD. Also, there are special features in the control word that handle the loading of the count value so that software overhead can be minimized for these functions.

The reading of the contents of each counter is available to the programmer with simple READ operations for event counting applications and special commands and logic are included in the 8253 so that the contents of each counter can be read "on the fly" without having to inhibit the clock input.

#### 8253 SYSTEM INTERFACE

The 8253 is a component of the Intel™ Microcomputer Systems and interfaces in the same manner as all other peripherals of the family. It is treated by the systems software as an array of peripheral №O ports; three are counters and the fourth is a control register for MODE programming.

Basically, the select inputs A0, A1 connect to the A0, A1 address bus signals of the CPU. The  $\overline{CS}$  can be derived directly from the address bus using a linear select method. Or it can be connected to the output of a decoder, such as an Intel® 8205 for larger systems.

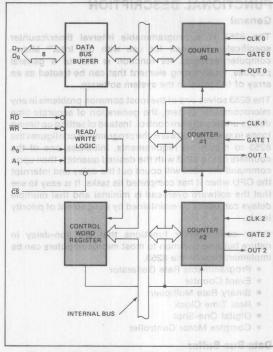

Figure 4. Block Diagram Showing Control Word Register and Counter Functions

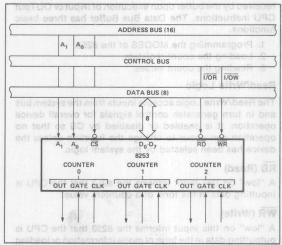

Figure 5. 8253 System Interface

#### OPERATIONAL DESCRIPTION

#### General

The complete functional definition of the 8253 is programmed by the systems software. A set of control words <u>must</u> be sent out by the CPU to initialize each counter of the 8253 with the desired MODE and quantity information. Prior to initialization, the MODE, count, and output of all counters is undefined. These control words program the MODE, Loading sequence and selection of binary or BCD counting.

Once programmed, the 8253 is ready to perform whatever timing tasks it is assigned to accomplish.

The actual counting operation of each counter is completely independent and additional logic is provided on-chip so that the usual problems associated with efficient monitoring and management of external, asynchronous events or rates to the microcomputer system have been eliminated.

#### **Programming the 8253**

All of the MODES for each counter are programmed by the systems software by simple I/O operations.

Each counter of the 8253 is individually programmed by writing a control word into the Control Word Register. (A0, A1 = 11)

#### Counter Loading

The count register is not loaded until the count value is written (one or two bytes, depending on the mode selected by the RL bits), followed by a rising edge and a falling edge of the clock. Any read of the counter prior to that falling clock edge may yield invalid data.

#### **MODE Definition**

MODE 0: Interrupt on Terminal Count. The output will be initially low after the mode set operation. After the count is loaded into the selected count register, the output will remain low and the counter will count. When terminal count is reached the output will go high and remain high until the selected count register is reloaded with the mode or a new count is loaded. The counter continues to decrement after terminal count has been reached.

Rewriting a counter register during counting results in the following:

- (1) Write 1st byte stops the current counting.
- (2) Write 2nd byte starts the new count.

MODE 1: Programmable One-Shot. The output will go low on the count following the rising edge of the gate input.

The output will go high on the terminal count. If a new count value is loaded while the output is low it will not affect the duration of the one-shot pulse until the succeeding trigger. The current count can be read at any time without affecting the one-shot pulse.

The one-shot is retriggerable, hence the output will remain low for the full count after any rising edge of the gate input.

number of input counts in the count register. If the count register is reloaded between output pulses the present period will not be affected, but the subsequent period will reflect the new value.

The gate input, when low, will force the output high. When the gate input goes high, the counter will start from the initial count. Thus, the gate input can be used to synchronize the counter.

When this mode is set, the output will remain high until after the count register is loaded. The output then can also be synchronized by software.

MODE 3: Square Wave Rate Generator. Similar to MODE 2 except that the output will remain high until one half the count has been completed (for even numbers) and go low for the other half of the count. This is accomplished by decrementing the counter by two on the falling edge of each clock pulse. When the counter reaches terminal count, the state of the output is changed and the counter is reloaded with the full count and the whole process is repeated.

If the count is odd and the output is high, the first clock pulse (after the count is loaded) decrements the count by 1. Subsequent clock pulses decrement the clock by 2. After timeout, the output goes low and the full count is reloaded. The first clock pulse (following the reload) decrements the counter by 3. Subsequent clock pulses decrement the count by 2 until timeout. Then the whole process is repeated. In this way, if the count is odd, the output will be high for (N + 1)/2 counts and low for (N - 1)/2 counts.

MODE 4: Software Triggered Strobe. After the mode is set, the output will be high. When the count is loaded, the counter will begin counting. On terminal count, the output will go low for one input clock period, then will go high again.

MODE 1: Programmable One-Shot. The outs

The output will go high on the terminal count. It a new count value is loaded while the output is low if will not affect the duration of the one-shot pulse until the succeeding trigger. The current count can be read at any

The one-shot is retriggerable, hence the output will remain low for the full count after any rising edge of the

white innibited while the gate input is low. Reloading the counter register will restart counting beginning with the new number.

MODE 5: Hardware Triggered Strobe. The counter will start counting after the rising edge of the trigger input and will go low for one clock period when the terminal count is reached. The counter is retriggerable. The output will not go low until the full count after the rising edge of any trigger.

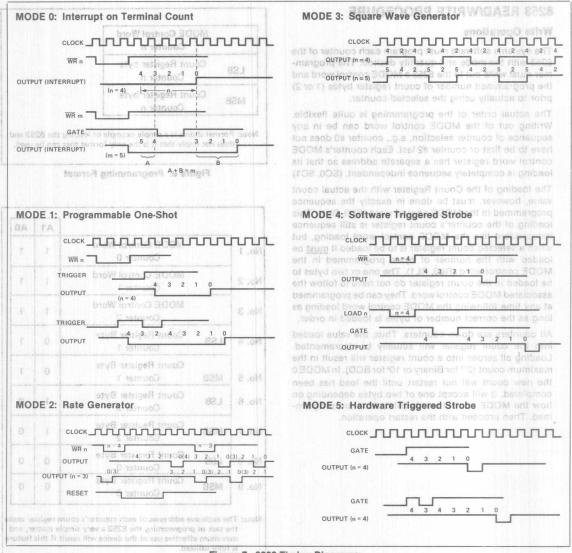

Figure 7. 8253 Timing Diagrams

#### 8253 READ/WRITE PROCEDURE

#### **Write Operations**

The systems software must program each counter of the 8253 with the mode and quantity desired. The programmer must write out to the 8253 a MODE control word and the programmed number of count register bytes (1 or 2) prior to actually using the selected counter.

The actual order of the programming is quite flexible. Writing out of the MODE control word can be in any sequence of counter selection, e.g., counter #0 does not have to be first or counter #2 last. Each counter's MODE control word register has a separate address so that its loading is completely sequence independent. (SC0, SC1)

The loading of the Count Register with the actual count value, however, must be done in exactly the sequence programmed in the MODE control word (RL0, RL1). This loading of the counter's count register is still sequence independent like the MODE control word loading, but when a selected count register is to be loaded it <u>must</u> be loaded with the number of bytes programmed in the MODE control word (RL0, RL1). The one or two bytes to be loaded in the count register do not have to follow the associated MODE control word. They can be programmed at any time following the MODE control word loading as long as the correct number of bytes is loaded in order.

All counters are down counters. Thus, the value loaded into the count register will actually be decremented. Loading all zeroes into a count register will result in the maximum count (216 for Binary or 104 for BCD). In MODE 0 the new count will not restart until the load has been completed. It will accept one of two bytes depending on how the MODE control words (RLO, RL1) are programmed. Then proceed with the restart operation.

uu	MODE Control Word Counter n
LSB	Count Register byte Counter n
MSB	Count Register byte Counter n

Note: Format shown is a simple example of loading the 8253 and does not imply that it is the only format that can be used.

No. 7	MSB	Count Register Byte Counter 2	0 1	0
No. 8	LSB	Count Register Byte Counter 0	0	0
No. 9	MSB	Count Register Byte Counter 0	0	0

Note: The exclusive addresses of each counter's count register make the task of programming the 8253 a very simple matter, and maximum effective use of the device will result if this feature is fully utilized.

Figure 9. Alternate Programming Formats

In most counter applications it becomes necessary to read the value of the count in progress and make a computational decision based on this quantity. Event counters are probably the most common application that uses this function. The 8253 contains logic that will allow the programmer to easily read the contents of any of the three counters without disturbing the actual count in progress.

There are two methods that the programmer can use to read the value of the counters. The first method involves the use of simple I/O read operations of the selected counter. By controlling the A0, A1 inputs to the 8253 the programmer can select the counter to be read (remember that no read operation of the mode register is allowed A0. A1-11). The only requirement with this method is that in order to assure a stable count reading the actual operation of the selected counter must be inhibited either by controlling the Gate input or by external logic that inhibits the clock input. The contents of the counter selected will be available as follows:

first I/O Read contains the least significant byte (LSB). second I/O Read contains the most significant byte (MSB).

Due to the internal logic of the 8253 it is absolutely necessary to complete the entire reading procedure. If two bytes are programmed to be read then two bytes must be read before any loading WR command can be sent to the same counter.

I Mai	1	0	Illegal inscission rework

#### **Reading While Counting**

In order for the programmer to read the contents of any counter without effecting or disturbing the counting operation the 8253 has special internal logic that can be accessed using simple WR commands to the MODE register. Basically, when the programmer wishes to read the contents of a selected counter "on the fly" he loads the MODE register with a special code which latches the present count value into a storage register so that its contents contain an accurate, stable quantity. The programmer then issues a normal read command to the selected counter and the contents of the latched register is available.

- **■** Binary or BCD Counting
- Single +5V Supply
- Uses HMOS Technology

The Intel® 8254 is a counter/timer device designed to solve the common timing control problems in microcomputer system design. It provides three independent 16-bit counters, each capable of handling clock inputs up to 10 MHz. All modes are software programmable.

The 8254 uses HMOS technology and comes in a 24-pin plastic or CERDIP package.

#### **FUNCTIONAL DESCRIPTION**

#### General

The 8254 is a programmable interval timer/counter designed for use with Intel microcomputer systems. It is a general purpose, multi-timing element that can be treated as an array of I/O ports in the system software.

The 8254 solves one of the most common problems in any microcomputer system, the generation of accurate time delays under software control. Instead of setting up timing loops in software, the programmer configures the 8254 to match his requirements and programs one of the counters for the desired delay. After the desired delay, the 8254 will interrupt the CPU. Software overhead is minimal and variable length delays can easily be accommodated.

Some of the other counter/timer functions common to microcomputers which can be implemented with the 8254 are:

- · Real time clock
- Event counter
- · Digital one-shot
- · Programmable rate generator
- · Square wave generator
- · Binary rate multiplier
- · Complex waveform generator
- · Complex motor controller

# **Block Diagram**

# DATA BUS BUFFER

This 3-state, bi-directional, 8-bit buffer is used to interface the 8254 to the system bus (see Figure 3).

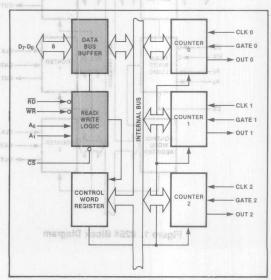

Figure 3. Block Diagram Showing Data Bus Buffer and Read/Write Logic Functions

#### READ/WRITE LOGICOTT 180230 JAMOS ARBOO

The Read/Write Logic accepts inputs from the system bus and generates control signals for the other functional blocks of the 8254. A<sub>1</sub> and A<sub>0</sub> select one of the three counters or the Control Word Register to be read from/written into, A "low" on the  $\overline{\text{RD}}$  input tells the 8254 that the CPU is reading one of the counters. A "low" on the  $\overline{\text{WR}}$  input tells the 8254 that the CPU is writing either a Control Word or an initial count. Both  $\overline{\text{RD}}$  and  $\overline{\text{WR}}$  are ignored unless the 8254 has been selected by holding  $\overline{\text{CS}}$  low.

#### CONTROL WORD REGISTER

The Control Word Register (see Figure 4) is selected by the Read/Write Logic when  $A_1, A_0 = 11$ . If the CPU then does a write operation to the 8254, the data is stored in the Control Word Register and is interpreted as a Control Word used to define the operation of the Counters.

The Control Word Register can only be written to; status information is available with the Read-Back Command.

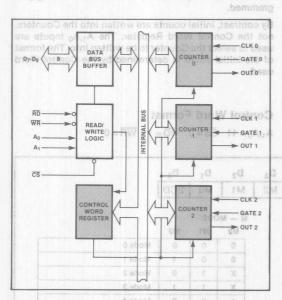

Figure 4. Block Diagram Showing Control Word Register and Counter Functions

#### **COUNTER 0, COUNTER 1, COUNTER 2**

These three functional blocks are identical in operation, so only a single Counter will be described. The internal block diagram of a single counter is shown in Figure 5.

The Counters are fully independent. Each Counter may operate in a different Mode.

The Control Word Register is shown in the figure; it is not part of the Counter itself, but its contents determine how the Counter operates.

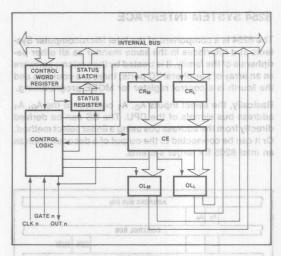

Figure 5. Internal Block Diagram of a Counter-

The status register, shown in the Figure, when latched, contains the current contents of the Control Word Register and status of the output and null count flag. (See detailed explanation of the Read-Back command.)

The actual counter is labelled CE (for "Counting Element"). It is a 16-bit presettable synchronous down counter.

 ${\sf OL_M}$  and  ${\sf OL_L}$  are two 8-bit latches. OL stands for "Output Latch"; the subscripts M and L stand for "Most significant byte" and "Least significant byte" respectively. Both are normally referred to as one unit and called just OL. These latches normally "follow" the CE, but if a suitable Counter Latch Command is sent to the 8254, the latches "latch" the present count until read by the CPU and then return to "following" the CE. One latch at a time is enabled by the counter's Control Logic to drive the internal bus. This is how the 16-bit Counter communicates over the 8-bit internal bus. Note that the CE itself cannot be read; whenever you read the count, it is the OL that is being read.

Similarly, there are two 8-bit registers called  $CR_M$  and  $CR_L$  (for "Count Register"). Both are normally referred to as one unit and called just CR. When a new count is written to the Counter, the count is stored in the CR and later transferred to the CE. The Control Logic allows one register at a time to be loaded from the internal bus. Both bytes are transferred to the CE simultaneously.  $CR_M$  and  $CR_L$  are cleared when the Counter is programmed. In this way, if the Counter has been programmed for one byte counts (either most significant byte only or least significant byte only) the other byte will be zero. Note that the CE cannot be written into; whenever a count is written, it is written into the CR.

e figure; it is

The Control Logic is also shown in the diagram. CLK n, ts determine

GATE n, and OUT n are all connected to the outside world through the Control Logic.

#### 8254 SYSTEM INTERFACE

The 8254 is a component of the Intel Microcomputer Systems and interfaces in the same manner as all other peripherals of the family. It is treated by the systems software as an array of peripheral I/O ports; three are counters and the fourth is a control register for MODE programming.

Basically, the select inputs  $A_0$ ,  $A_1$  connect to the  $A_0$ ,  $A_1$  address bus signals of the CPU. The CS can be derived directly from the address bus using a linear select method. Or it can be connected to the output of a decoder, such as an Intel 8205 for larger systems.

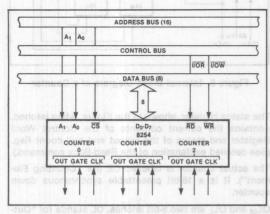

Figure 6. 8254 System Interface

#### OPERATIONAL DESCRIPTION

# General o theies AA bas AA A828 ent to shoold landit

After power-up, the state of the 8254 is undefined. The Mode, count value, and output of all Counters are undefined.

How each Counter operates is determined when it is programmed. Each Counter must be programmed before it can be used. Unused counters need not be programmed.

## Programming the 8254 north placed with Whose R and

Counters are programmed by writing a Control Word and then an initial count.

All Control Words are written into the Control Word Register, which is selected when  $A_1,A_0=11$ . The Control Word itself specifies which Counter is being programmed.

By contrast, initial counts are written into the Counters, not the Control Word Register. The  $A_1,A_0$  inputs are used to select the Counter to be written into. The format of the initial count is determined by the Control Word used.

Figure 7. Control Word Format

# Write Operations and at Naca ent to enumed rentionA

The programming procedure for the 8254 is very flexible. Only two conventions need to be remembered:

- For each Counter, the Control Word must be written before the initial count is written.
- 2) The initial count must follow the count format specified in the Control Word (least significant byte only, most significant byte only, or least significant byte and then most significant byte).

Since the Control Word Register and the three Counters have separate addresses (selected by the A<sub>1</sub>,A<sub>0</sub> inputs), and each Control Word specifies the Counter it applies to (SC0,SC1 bits), no special instruction sequence is re-

quired. Any programming sequence that follows the conventions above is acceptable.

A new initial count may be written to a Counter at any time without affecting the Counter's programmed Mode in any way. Counting will be affected as described in the Mode definitions. The new count must follow the programmed count format.

If a Counter is programmed to read/write two-byte counts, the following precaution applies: A program must not transfer control between writing the first and second byte to another routine which also writes into that same Counter. Otherwise, the Counter will be loaded with an incorrect count.

#### **Read Operations**

It is often desirable to read the value of a Counter without disturbing the count in progress. This is easily done in the 8254.

There are three possible methods for reading the Counters. The first is through the Read-Back command,

which is explained later. The second is a simple read operation of the Counter, which is selected with the A<sub>1</sub>,A<sub>0</sub> inputs. The only requirement is that the CLK input of the selected Counter must be inhibited by using either the GATE input or external logic. Otherwise, the count may be in process of changing when it is read, giving an undefined result.

# int a lanca access

The other method involves a special software command called the "Counter Latch Command". Like a Control Word, this command is written to the Control Word Register, which is selected when  $A_1, A_0 = 11$ . Also like a Control Word, the SC0,SC1 bits select one of the three Counters, but two other bits, D5 and D4, distinguish this command from a Control Word.

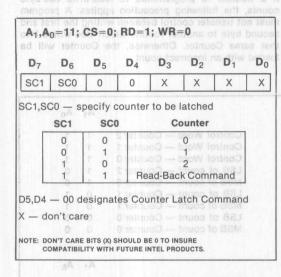

Figure 9. Counter Latching Command Format

The selected Counter's output latch (OL) latches the count at the time the Counter Latch Command is received. This count is held in the latch until it is read by the CPU (or until the Counter is reprogrammed). The count is then unlatched automatically and the OL returns to "following" the counting element (CE). This allows reading the contents of the Counters "on the fly" without affecting counting in progress. Multiple Counter Latch Commands may be used to latch more than one Counter. Each latched Counter's OL holds its count until it is read. Counter Latch Commands do not affect the programmed Mode of the Counter in any way.

If a Counter is latched and then, some time later, latched again before the count is read, the second Counter Latch Command is ignored. The count read will be the count at the time the first Counter Latch Command was issued.

With either method, the count must be read according to the programmed format; specifically, if the Counter is programmed for two byte counts, two bytes must be read. The two bytes do not have to be read one right after the other; read or write or programming operations of other Counters may be inserted between them.

Another feature of the 8254 is that reads and writes of the same Counter may be interleaved; for example, if the Counter is programmed for two byte counts, the following sequence is valid.

- 1. Read least significant byte.
- 2. Write new least significant byte.
- 3. Read most significant byte.
  - 4. Write new most significant byte.

If a Counter is programmed to read/write two-byte counts, the following precaution applies: A program must not transfer control between reading the first and second byte to another routine which also reads from that same Counter. Otherwise, an incorrect count will be read.

#### **READ-BACK COMMAND**

The read-back command allows the user to check the count value, programmed Mode, and current state of the OUT pin and Null Count flag of the selected counter(s).

The command is written into the Control Word Register and has the format shown in Figure 10. The command applies to the counters selected by setting their corresponding bits D3,D2,D1=1.

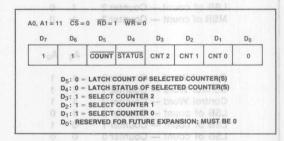

Figure 10. Read-Back Command Format

The read-back command may be used to latch multiple counter output latches (OL) by setting the  $\overline{\text{COUNT}}$  bit D5=0 and selecting the desired counter(s). This single command is functionally equivalent to several counter latch commands, one for each counter latched. Each counter's latched count is held until it is read (or the counter is reprogrammed). That counter is automatically unlatched when read, but other counters remain latched until they are read. If multiple count read-back commands are issued to the same counter without reading the count, all but the first are ignored; i.e., the count which will be read is the count at the time the first read-back command was issued.

The read-back command may also be used to latch status information of selected counter(s) by setting STATUS bit D4 = 0. Status must be latched to be read; status of a counter is accessed by a read from that counter.

The counter status format is shown in Figure 11. Bits D5 through D0 contain the counter's programmed Mode exactly as written in the last Mode Control Word. OUTPUT bit D7 contains the current state of the OUT pin. This allows the user to monitor the counter's output via software, possibly eliminating some hardware from a system.

							D <sub>0</sub>
DUTPUT	COUNT	RW1	RW0	M2 0	M1	MO	BCD
	COUNT						A
	D <sub>7</sub> 1 = 0	UT PIN	IS 1				
-	De 1 = N	ULL CO					

Figure 11. Status Byte

NULL COUNT bit D6 indicates when the last count written to the counter register (CR) has been loaded into the counting element (CE). The exact time this happens depends on the Mode of the counter and is described in the Mode Definitions, but until the count is loaded into the counting element (CE), it can't be read from the counter. If the count is latched or read before this time, the count value will not reflect the new count just written. The operation of Null Count is shown in Figure 12.

	THIS ACTION:	CAUSES:
A.	WRITE TO THE CONTROL WORD REGISTER:[1]	NULL COUNT=1
B.	WRITE TO THE COUNT REGISTER (CR);[2]	NULL COUNT=1

[2]	IF THE COUNTER IS PROGRAMMED FOR TWO-E SIGNIFICANT BYTE THEN MOST SIGNIFICANT GOES TO 1 WHEN THE SECOND BYTE IS WRITT	BYTE) NULL COU

Figure 12. Null Count Operation

If multiple status latch operations of the counter(s) are performed without reading the status, all but the first are ignored; i.e., the status that will be read is the status of the counter at the time the first status read-back command was issued.

Both count and status of the selected counter(s) may be latched simultaneously by setting both COUNT and STATUS bits D5,D4=0. This is functionally the same as issuing two separate read-back commands at once, and the above discussions apply here also. Specifically, if multiple count and/or status read-back commands are issued to the same counter(s) without any intervening reads, all but the first are ignored. This is illustrated in Figure 13.

D <sub>7</sub>	D <sub>6</sub>	D <sub>5</sub>	_	mano D <sub>3</sub>	D <sub>2</sub>	D <sub>1</sub>	D <sub>0</sub>	Description at ages palls	Result

Figure 13. Read-Back Command Example and Island bras broty to ting our settle

If both count and status of a counter are latched, the first read operation of that counter will return latched status, regardless of which was latched first. The next one or two reads (depending on whether the counter is programmed for one or two type counts) return latched count. Subsequent reads return unlatched count.

Figure 14. Read/Write Operations Summary

#### **Mode Definitions**

The following are defined for use in describing the operation of the 8254.

CLK pulse: a rising edge, then a falling edge, in that order, of a Counter's CLK input.

trigger: a rising edge of a Counter's GATE input.

Counter loading: the transfer of a count from the CR to the CE (refer to the "Functional Description")

#### MODE 0: INTERRUPT ON TERMINAL COUNT

Mode 0 is typically used for event counting. After the Control Word is written, OUT is initially low, and will remain low until the Counter reaches zero. OUT then goes high and remains high until a new count or a new Mode 0 Control Word is written into the Counter.

GATE=1 enables counting; GATE=0 disables counting. GATE has no effect on OUT.

After the Control Word and initial count are written to a Counter, the initial count will be loaded on the next CLK pulse. This CLK pulse does not decrement the count, so for an initial count of N, OUT does not go high until N + 1 CLK pulses after the initial count is written.

If a new count is written to the Counter, it will be loaded on the next CLK pulse and counting will continue from the new count. If a two-byte count is written, the following happens:

- Writing the first byte disables counting. OUT is set low immediately (no clock pulse required)
- 2) Writing the second byte allows the new count to be loaded on the next CLK pulse.

This allows the counting sequence to be synchronized by software. Again, OUT does not go high until N+1 CLK pulses after the new count of N is written.

If an initial count is written while GATE = 0, it will still be loaded on the next CLK pulse. When GATE goes high, OUT will go high N CLK pulses later; no CLK pulse is needed to load the Counter as this has already been done.

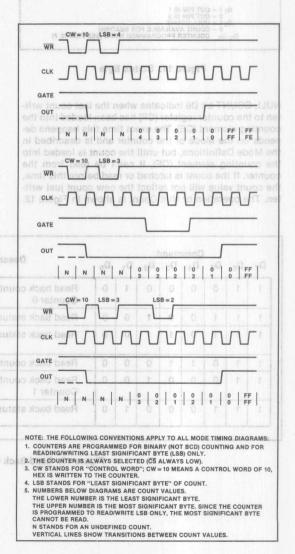

Figure 15. Mode 0

#### MODE 1: HARDWARE RETRIGGERABLE ONE-SHOT

OUT will be initially high. OUT will go low on the CLK pulse following a trigger to begin the one-shot pulse, and will remain low until the Counter reaches zero. OUT will then go high and remain high until the CLK pulse after the next trigger.

After writing the Control Word and initial count, the Counter is armed. A trigger results in loading the Counter and setting OUT low on the next CLK pulse, thus starting the one-shot pulse. An initial count of N will result in a one-shot pulse N CLK cycles in duration. The one-shot is retriggerable, hence OUT will remain low for N CLK pulses after any trigger. The one-shot pulse can be repeated without rewriting the same count into the counter. GATE has no effect on OUT.

If a new count is written to the Counter during a oneshot pulse, the current one-shot is not affected unless the Counter is retriggered. In that case, the Counter is loaded with the new count and the one-shot pulse continues until the new count expires.

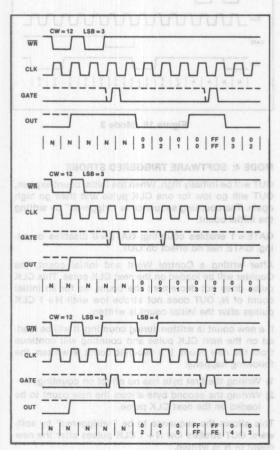

Figure 16. Mode 1

# MODE 2: RATE GENERATOR

This Mode functions like a divide-by-N counter. It is typically used to generate a Real Time Clock interrupt. OUT will initially be high. When the initial count has decremented to 1, OUT goes low for one CLK pulse. OUT then goes high again, the Counter reloads the initial count and the process is repeated. Mode 2 is periodic; the same sequence is repeated indefinitely. For an initial count of N, the sequence repeats every N CLK cycles.

GATE = 1 enables counting; GATE = 0 disables counting. If GATE goes low during an output pulse, OUT is set high immediately. A trigger reloads the Counter with the initial count on the next CLK pulse; OUT goes low N CLK pulses after the trigger. Thus the GATE input can be used to synchronize the Counter.

After writing a Control Word and initial count, the Counter will be loaded on the next CLK pulse. OUT goes low N CLK Pulses after the initial count is written. This allows the Counter to be synchronized by software also.

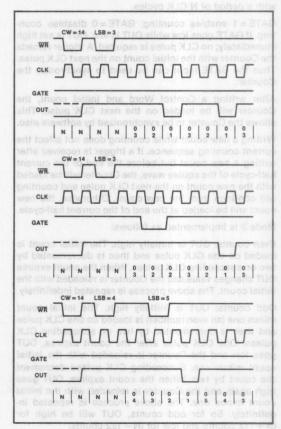

Figure 17. Mode 2

writing a new count but before the end of the current period, the Counter will be loaded with the new count on the next CLK pulse and counting will continue from the new count. Otherwise, the new count will be loaded at the end of the current counting cycle.

the same sequence is repeated indefinitely. For an Initial count of N, the sequence repeats every N CLK

GATE = 1 enables counting; GATE = 0 disables counting, if GATE goes low during an output pulse, OUT is set high immediately. A trigger reloads the Counter with the initial count on the next CLK pulse; OUT goes low N OLK pulses after the trigger. Thus the GATE input can

#### MODE 3: SQUARE WAVE MODE

Mode 3 is typically used for Baud rate generation. Mode 3 is similar to Mode 2 except for the duty cycle of OUT. OUT will initially be high. When half the initial count has expired, OUT goes low for the remainder of the count. Mode 3 is periodic; the sequence above is repeated indefinitely. An initial count of N results in a square wave with a period of N CLK cycles.

GATE = 1 enables counting; GATE = 0 disables counting. If GATE goes low while OUT is low, OUT is set high immediately; no CLK pulse is required. A trigger reloads the Counter with the initial count on the next CLK pulse. Thus the GATE input can be used to synchronize the Counter.

After writing a Control Word and initial count, the Counter will be loaded on the next CLK pulse. This allows the Counter to be synchronized by software also.

Writing a new count while counting does not affect the current counting sequence. If a trigger is received after writing a new count but before the end of the current half-cycle of the square wave, the Counter will be loaded with the new count on the next CLK pulse and counting will continue from the new count. Otherwise, the new count will be loaded at the end of the current half-cycle.

Mode 3 is implemented as follows:

Even counts: OUT is initially high. The initial count is loaded on one CLK pulse and then is decremented by two on succeeding CLK pulses. When the count expires OUT changes value and the Counter is reloaded with the initial count. The above process is repeated indefinitely.

Odd counts: OUT is initially high. The initial count minus one (an even number) is loaded on one CLK pulse and then is decremented by two on succeeding CLK pulses. One CLK pulse after the count expires, OUT goes low and the Counter is reloaded with the initial count minus one. Succeeding CLK pulses decrement the count by two. When the count expires, OUT goes high again and the Counter is reloaded with the initial count minus one. The above process is repeated indefinitely. So for odd counts, OUT will be high for (N+1)/2 counts and low for (N-1)/2 counts.

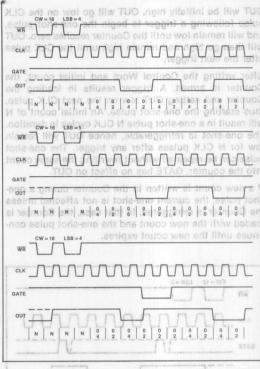

Figure 18. Mode 3

#### **MODE 4: SOFTWARE TRIGGERED STROBE**

OUT will be initially high. When the initial count expires, OUT will go low for one CLK pulse and then go high again. The counting sequence is "triggered" by writing the initial count.

GATE = 1 enables counting; GATE = 0 disables counting. GATE has no effect on OUT.

After writing a Control Word and initial count, the Counter will be loaded on the next CLK pulse. This CLK pulse does not decrement the count, so for an initial count of N, OUT does not strobe low until N+1 CLK pulses after the initial count is written.

If a new count is written during counting, it will be loaded on the next CLK pulse and counting will continue from the new count. If a two-byte count is written, the following happens:

- 1) Writing the first byte has no effect on counting.
- 2) Writing the second byte allows the new count to be loaded on the next CLK pulse.

This allows the sequence to be "retriggered" by software. OUT strobes low N + 1 CLK pulses after the new count of N is written.

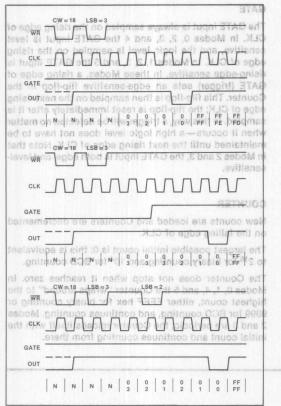

Figure 19. Mode 4

# MODE 5: HARDWARE TRIGGERED STROBE (RETRIGGERABLE)

OUT will initially be high. Counting is triggered by a rising edge of GATE. When the initial count has expired, OUT will go low for one CLK pulse and then go high again.

After writing the Control Word and initial count, the counter will not be loaded until the CLK pulse after a trigger. This CLK pulse does not decrement the count, so for an initial count of N, OUT does not strobe low until N+1 CLK pulses after a trigger.

A trigger results in the Counter being loaded with the initial count on the next CLK pulse. The counting sequence is retriggerable. OUT will not strobe low for N+1 CLK pulses after any trigger. GATE has no effect on OUT.

If a new count is written during counting, the curent counting sequence will not be affected. If a trigger occurs after the new count is written but before the current count expires, the Counter will be loaded with the new count on the next CLK pulse and counting will continue from there.

Figure 22. Minimum and Maximum Initial Counts

# **Operation Common to All Modes**

#### **PROGRAMMING**

When a Control Word is written to a Counter, all Control Logic is immediately reset and OUT goes to a known initial state; no CLK pulses are required for this.

#### GATE

The GATE input is always sampled on the rising edge of CLK. In Modes 0, 2, 3, and 4 the GATE input is level sensitive, and the logic level is sampled on the rising edge of CLK. In Modes 1, 2, 3, and 5 the GATE input is rising-edge sensitive. In these Modes, a rising edge of GATE (trigger) sets an edge-sensitive flip-flop in the Counter. This flip-flop is then sampled on the next rising edge of CLK; the flip-flop is reset immediately after it is sampled. In this way, a trigger will be detected no matter when it occurs—a high logic level does not have to be maintained until the next rising edge of CLK. Note that in Modes 2 and 3, the GATE input is both edge- and level-sensitive.

#### COUNTER

New counts are loaded and Counters are decremented on the falling edge of CLK.

The largest possible initial count is 0; this is equivalent to 2<sup>16</sup> for binary counting and 10<sup>4</sup> for BCD counting.

The Counter does not stop when it reaches zero. In Modes 0, 1, 4, and 5 the Counter "wraps around" to the highest count, either FFFF hex for binary counting or 9999 for BCD counting, and continues counting. Modes 2 and 3 are periodic; the Counter reloads itself with the initial count and continues counting from there.

# 8255A/8255A-5 PROGRAMMABLE PERIPHERAL INTERFACE

- MCS-85<sup>TM</sup> Compatible 8255A-5
- 24 Programmable I/O Pins
- **Completely TTL Compatible**
- Fully Compatible with Intel® Microprocessor Families
- Improved Timing Characteristics

- Direct Bit Set/Reset Capability Easing
   Control Application Interface
- 40-Pin Dual In-Line Package
- Reduces System Package Count
- Improved DC Driving Capability

The Intel® 8255A is a general purpose programmable I/O device designed for use with Intel® microprocessors. It has 24 I/O pins which may be individually programmed in 2 groups of 12 and used in 3 major modes of operation. In the first mode (MODE 0), each group of 12 I/O pins may be programmed in sets of 4 to be input or output. In MODE 1, the second mode, each group may be programmed to have 8 lines of input or output. Of the remaining 4 pins, 3 are used for handshaking and interrupt control signals. The third mode of operation (MODE 2) is a bidirectional bus mode which uses 8 lines for a bidirectional bus, and 5 lines, borrowing one from the other group, for handshaking.

1-333

#### General na . E . A) anog fid-8 parti anistrop A2658 and

The 8255A is a programmable peripheral interface (PPI) device designed for use in Intel® microcomputer systems. Its function is that of a general purpose I/O component to interface peripheral equipment to the microcomputer system bus. The functional configuration of the 8255A is programmed by the system software so that normally no external logic is necessary to interface peripheral devices or structures.

#### **Data Bus Buffer**

This 3-state bidirectional 8-bit buffer is used to interface the 8255A to the system data bus. Data is transmitted or received by the buffer upon execution of input or output instructions by the CPU. Control words and status information are also transferred through the data bus buffer.

# Read/Write and Control Logic

The function of this block is to manage all of the internal and external transfers of both Data and Control or Status words. It accepts inputs from the CPU Address and Control busses and in turn, issues commands to both of the Control Groups.

# (CS)

Chip Select. A "low" on this input pin enables the communiction between the 8255A and the CPU.

send the data or status information to the CPU on the data bus. In essence, it allows the CPU to "read from" the 8255A.

# (WR)

Write. A "low" on this input pin enables the CPU to write data or control words into the 8255A.

# (Ao and A1) upitros tenditorut ent socilatiful ferit cote

Port Select 0 and Port Select 1. These input signals, in conjunction with the RD and WR inputs, control the selection of one of the three ports or the control word registers. They are normally connected to the least significant bits of the address bus (A<sub>0</sub> and A<sub>1</sub>).

#### (RESET)

Reset. A "high on this input clears the control register and all ports (A, C, C) are set to the input mode.

#### Group A and Group B Controls

The functional configuration of each port is programmed by the systems software. In essence, the CPU "outputs" a control word to the 8255A. The control word contains information such as "mode", "bit set", "bit reset", etc., that initializes the functional configuration of the 8255A.

Each of the Control blocks (Group A and Group B) accepts "commands" from the Read/Write Control Logic, receives "control words" from the internal data bus and issues the proper commands to its associated ports.

Control Group A — Port A and Port C upper (C7-C4) Control Group B — Port B and Port C lower (C3-C0)

The Control Word Register can Only be written into. No Read operation of the Control Word Register is allowed.

# Ports A, B, and C

The 8255A contains three 8-bit ports (A, B, and C). All can be configured in a wide variety of functional characteristics by the system software but each has its own special features or "personality" to further enhance the power and flexibility of the 8255A.

Port A. One 8-bit data output latch/buffer and one 8-bit data input latch. An ai olgo issue ixe on vilsimon ferit oa

Port B. One 8-bit data input/output latch/buffer and one 8-bit data input buffer.

Port C. One 8-bit data output latch/buffer and one 8-bit data input buffer (no latch for input). This port can be divided into two 4-bit ports under the mode control. Each 4-bit port contains a 4-bit latch and it can be used for the control signal outputs and status signal inputs in conjunction with ports A and B.

Figure 3. 8255A Block Diagram Showing Data Bus Buffer and Read/Minte Control Logic Functions

#### **Mode Selection**

There are three basic modes of operation that can be selected by the system software:

When Port C Is being used as status/control for Port A or B.

- Mode 0 - Basic Input/Output Jugni (seuper Journal)

Mode 1 - Strobed Input/Output stereo alsopia leaup

Mode 2 - Bi-Directional Bus and patter ve belowie

When the reset input goes "high" all ports will be set to the input mode (i.e., all 24 lines will be in the high impedance state). After the reset is removed the 8255A can remain in the input mode with no additional initialization required. During the execution of the system program any of the other modes may be selected using a single output instruction. This allows a single 8255A to service a variety of peripheral devices with a simple software maintenance routine.

The modes for Port A and Port B can be separately defined, while Port C is divided into two portions as required by the Port A and Port B definitions. All of the output registers, including the status flip-flops, will be reset whenever the mode is changed. Modes may be combined so that their functional definition can be "tailored" to almost any I/O structure. For instance; Group B can be programmed in Mode 0 to monitor simple switch closings or display computational results, Group A could be programmed in Mode 1 to monitor a keyboard or tape reader on an interrupt-driven basis.

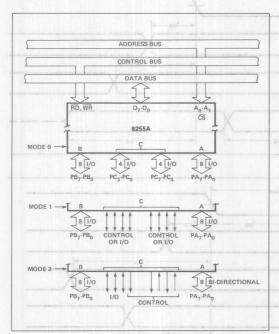

Figure 5. Basic Mode Definitions and Bus Interface

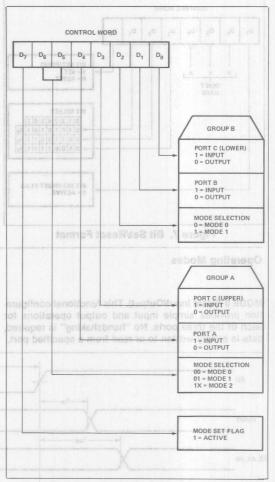

Figure 6. Mode Definition Format

The mode definitions and possible mode combinations may seem confusing at first but after a cursory review of the complete device operation a simple, logical I/O approach will surface. The design of the 8255A has taken into account things such as efficient PC board layout, control signal definition vs PC layout and complete functional flexibility to support almost any peripheral device with no external logic. Such design represents the maximum use of the available pins.

#### Single Bit Set/Reset Feature

Any of the eight bits of Port C can be Set or Reset using a single OUTput instruction. This feature reduces software requirements in Control-based applications.

1-336 AFN-00744B

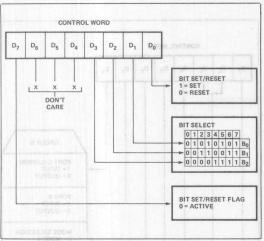

Figure 7. Bit Set/Reset Format

# **Operating Modes**

MODE 0 (Basic Input/Output). This functional configuration provides simple input and output operations for each of the three ports. No "handshaking" is required, data is simply written to or read from a specified port.

When Port C is being used as status/control for Port A or B, these bits can be set or reset by using the Bit Set/Reset operation just as if they were data output ports.

# Interrupt Control Functions

When the 8255A is programmed to operate in mode 1 or mode 2, control signals are provided that can be used as interrupt request inputs to the CPU. The interrupt request signals, generated from port C, can be inhibited or enabled by setting or resetting the associated INTE flipflop, using the bit set/reset function of port C.

This function allows the Programmer to disallow or allow a specific I/O device to interrupt the CPU without affecting any other device in the interrupt structure.

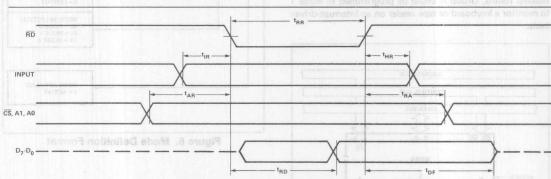

INTE flip-flop definition: Clubexe sat pahud berlupen

(BIT-SET) - INTE is SET - Interrupt enable (BIT-RESET) - INTE is RESET - Interrupt disable

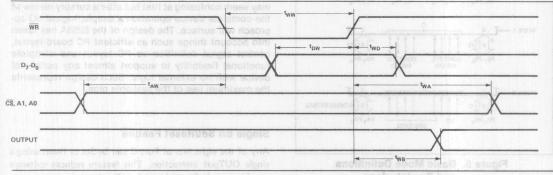

Note: All Mask flip-flops are automatically reset during mode selection and device Reset.

Mode 0 Basic Functional Definitions:

- Two 8-bit ports and two 4-bit ports.
- Any port can be input or output.
- Outputs are latched.
- Inputs are not latched.
- 16 different Input/Output configurations are possible in this Mode.

## **Operating Modes**

MODE 1 (Strobed Input/Output). This functional configuration provides a means for transferring I/O data to or from a specified port in conjunction with strobes or "handshaking" signals. In mode 1, port A and Port B use the lines on port C to generate or accept these "handshaking" signals.

#### Mode 1 Basic Functional Definitions:

- Two Groups (Group A and Group B)
- Each group contains one 8-bit data port and one 4-bit control/data port.
- The 8-bit data port can be either input or output.
   Both inputs and outputs are latched.
- The 4-bit port is used for control and status of the 8-bit data port.

Figure 9, MODE 1 (Strobed Input)

# **Input Control Signal Definition**

STB (Strobe Input). A "low" on this input loads data into the input latch.

# IBF (Input Buffer Full F/F)

A "high" on this output indicates that the data has been loaded into the input latch; in essence, an acknowledgement IBF is set by STB input being low and is reset by the rising edge of the RD input.

# **INTR** (Interrupt Request)

A "high" on this output can be used to interrupt the CPU when an input device is requesting service. INTR is set by the  $\overline{STB}$  is a "one", IBF is a "one" and INTE is a "one". It is reset by the falling edge of  $\overline{RD}$ . This procedure allows an input device to request service from the CPU by simply strobing its data into the port.

INTE A

Controlled by bit set/reset of PC4.

INTE B

Controlled by bit set/reset of PC2.

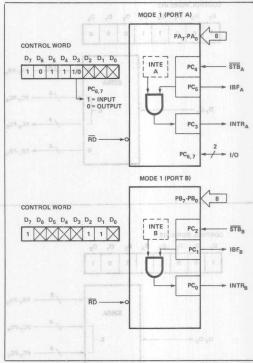

Figure 8. MODE 1 Input

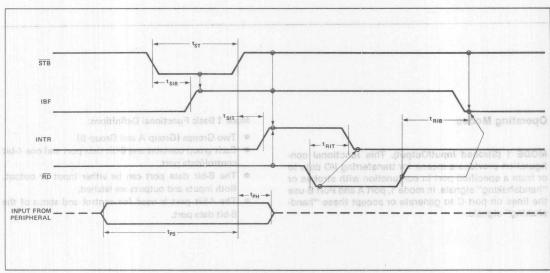

Figure 9. MODE 1 (Strobed Input)

## **Output Control Signal Definition**

OBF (Output Buffer Full F/F). The OBF output will go "low" to indicate that the CPU has written data out to the specified port. The OBF F/F will be set by the rising edge of the WR input and reset by ACK Input being low.

ACK (Acknowledge Input). A "low" on this input informs the 8255A that the data from port A or port B has been accepted. In essence, a response from the peripheral device indicating that it has received the data output by the CPU.

INTR (Interrupt Request). A "high" on this output can be used to interrupt the CPU when an output device has accepted data transmitted by the CPU. INTR is set when ACK is a "one", OBF is a "one" and INTE is a "one". It is reset by the falling edge of WR.

INTEA

Controlled by bit set/reset of PC6.

INTE B

Controlled by bit set/reset of PC2.

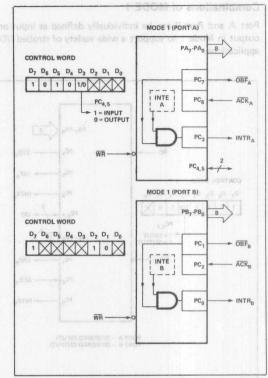

Figure 10. MODE 1 Output

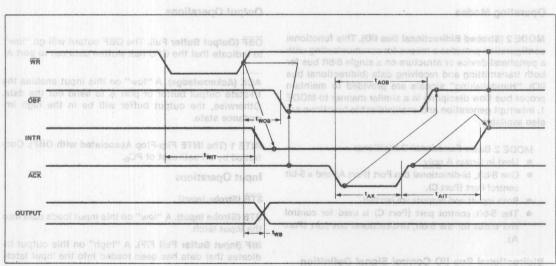

Figure 11. Mode 1 (Strobed Output)

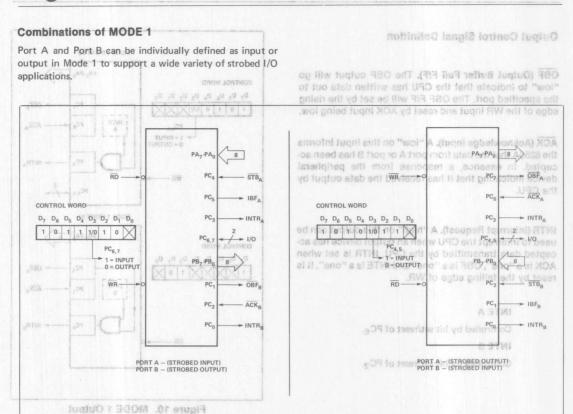

Figure 12. Combinations of MODE 1

#### **Operating Modes**

MODE 2 (Strobed Bidirectional Bus I/O). This functional configuration provides a means for communicating with a peripheral device or structure on a single 8-bit bus for both transmitting and receiving data (bidirectional bus I/O). "Handshaking" signals are provided to maintain proper bus flow discipline in a similar manner to MODE 1. Interrupt generation and enable/disable functions are also available.

#### MODE 2 Basic Functional Definitions:

- Used in Group A only.
- One 8-bit, bi-directional bus Port (Port A) and a 5-bit control Port (Port C).
- Both inputs and outputs are latched.
- The 5-bit control port (Port C) is used for control and status for the 8-bit, bi-directional bus port (Port A).

# Bidirectional Bus I/O Control Signal Definition

**INTR (Interrupt Request).** A high on this output can be used to interrupt the CPU for both input or output operations.

#### **Output Operations**

OBF (Output Buffer Ful). The OBF output will go "low" to indicate that the CPU has written data out to port A.

ACK (Acknowledge). A "low" on this input enables the tri-state output buffer of port A to send out the data. Otherwise, the output buffer will be in the high impedance state.

INTE 1 (The INTE Flip-Flop Associated with OBF). Controlled by bit set/reset of PC<sub>6</sub>.

#### **Input Operations**

#### STB (Strobe Input)

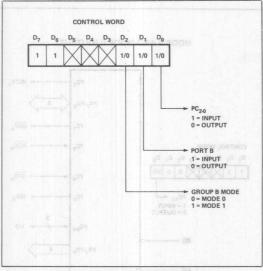

STB (Strobe Input). A "low" on this input loads data into the input latch.

**IBF (Input Buffer Full F/F).** A "high" on this output indicates that data has been loaded into the input latch.

#### **Special Mode Combination Considerations**

There are several combinations of modes when not all of the bits in Port C are used for control or status. The remaining bits can be used as follows:

If Programmed as Inputs -

All input lines can be accessed during a normal Port C read.

If Programmed as Outputs -

Bits in C upper (PC<sub>7</sub>-PC<sub>4</sub>) must be individually accessed using the bit set/reset function.

Bits in C lower (PC<sub>3</sub>-PC<sub>0</sub>) can be accessed using the bit set/reset function or accessed as a threesome by writing into Port C.

## Source Current Capability on Port B and Port C

Any set of eight output buffers, selected randomly from Ports B and C can source 1mA at 1.5 volts. This feature allows the 8255 to directly drive Darlington type drivers and high-voltage displays that require such source current.

#### Reading Port C Status

In Mode 0, Port C transfers data to or from the peripheral device. When the 8255 is programmed to function in Modes 1 or 2, Port C generates or accepts "hand-shaking" signals with the peripheral device. Reading the contents of Port C

allows the programmer to test or verify the "status" of each peripheral device and change the program flow accordingly.

APPLICATIONS OF THE 8255A

There is no special instruction to read the status information from Port C. A normal read operation of Port C is executed to perform this function.

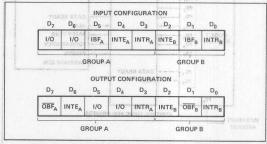

Figure 17. MODE 1 Status Word Format

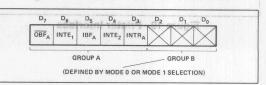

Figure 18. MODE 2 Status Word Format

#### **APPLICATIONS OF THE 8255A**

The 8255A is a very powerful tool for interfacing peripheral equipment to the microcomputer system. It represents the optimum use of available pins and is flexible enough to interface almost any I/O device without the need for additional external logic.

Each peripheral device in a microcomputer system usually has a "service routine" associated with it. The routine manages the software interface between the device and the CPU. The functional definition of the 8255A is programmed by the I/O service routine and becomes an extension of the system software. By examining the I/O devices interface characteristics for both data transfer and timing, and matching this information to the examples and tables in the detailed operational description, a control word can easily be developed to initialize the 8255A to exactly "fit" the application. Figures 19 through 25 present a few examples of typical applications of the 8255A.

The Intel® 8275 Programmable CRT Controller is a single chip device to interface CRT raster scan displays with Intel® microcomputer systems. Its primary function is to refresh the display by buffering the information from main memory and keeping track of the display position of the screen. The flexibility designed into the 8275 will allow simple interface to almost any raster scan CRT display with a minimum of external hardware and software overhead.

#### **Data Bus Buffer**

This 3-state, bidirectional, 8-bit buffer is used to interface the 8275 to the system Data Bus.

This functional block accepts inputs from the System Control Bus and generates control signals for overall device operation. It contains the Command, Parameter, and Status Registers that store the various control formats for the device functional definition.

A <sub>0</sub>	OPERATION	REGISTER
0	Read	PREG
0	Write	PREG
1	Read	SREG
1 00	Write	CREG

#### RD (Read)

A "low" on this input informs the 8275 that the CPU is reading data or status information from the 8275.

## WR (Write)

A "low" on this input informs the 8275 that the CPU is writing data or control words to the 8275.

## CS (Chip Select)

A "low" on this input selects the 8275. No reading or writing will occur unless the device is selected. When  $\overline{CS}$  is high, the Data Bus in the float state and  $\overline{RD}$  and  $\overline{WR}$  will have no effect on the chip.

## DRQ (DMA Request) house of tugue of the land and

A "high" on this output informs the DMA Controller that the 8275 desires a DMA transfer.

## DACK (DMA Acknowledge) 12 got2-next2 to bn3"

A "low" on this input informs the 8275 that a DMA cycle is in progress.

## **IRQ** (Interrupt Request)

A "high" on this output informs the CPU that the 8275 desires interrupt service.

X	1	1	0	Three-State
X	X	X	1	Three-state

#### **Character Counter**

The Character Counter is a programmable counter that is used to determine the number of characters to be displayed per row and the length of the horizontal retrace interval. It is driven by the CCLK (Character Clock) input, which should be a derivative of the external dot clock.

#### **Line Counter**

The Line Counter is a programmable counter that is used to determine the number of horizontal lines (Sweeps) per character row. Its outputs are used to address the external character generator ROM.

#### **Row Counter**

The Row Counter is a programmable counter that is used to determine the number of character rows to be displayed per frame and length of the vertical retrace interval.

## Light Pen Registers

The Light Pen Registers are two registers that store the contents of the character counter and the row counter whenever there is a rising edge on the LPEN (Light Pen) input.

Note: Software correction is required.

## **Raster Timing and Video Controls**

The Raster Timing circuitry controls the timing of the HRTC (Horizontal Retrace) and VRTC (Vertical Retrace) outputs. The Video Control circuitry controls the generation of  $LA_{0-1}$  (Line Attribute), HGLT (Highlight), RVV (Reverse Video), LTEN (Light Enable), VSP (Video Suppress), and  $GPA_{0-1}$  (General Purpose Attribute) outputs.

## Row Buffers and all series

The Row Buffers are two 80 character buffers. They are filled from the microcomputer system memory with the character codes to be displayed. While one row buffer is displaying a row of characters, the other is being filled with the next row of characters.

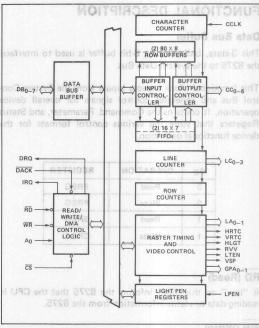

Figure 4. 8275 Block Diagram Showing Counter and Register Functions

#### **FIFOs**

There are two 16 character FIFOs in the 8275. They are used to provide extra row buffer length in the Transparent Attribute Mode (see Detailed Operation section).

## **Buffer Input/Output Controllers**

The Buffer Input/Output Controllers decode the characters being placed in the row buffers. If the character is a character attribute, field attribute or special code, these controllers control the appropriate action. (Examples: An "End of Screen—Stop DMA" special code will cause the Buffer Input Controller to stop further DMA requests. A "Highlight" field attribute will cause the Buffer Output Controller to activate the HGLT output.)

A "high" on this output informs the CPU that the 8275

## SYSTEM OPERATION and tog somil to redmun and

The 8275 is programmable to a large number of different display formats. It provides raster timing, display row buffering, visual attribute decoding, cursor timing, and light pen detection.

tion, and blanking of top a

It is designed to interface with the 8257 DMA Controller and standard character generator ROMs for dot matrix decoding. Dot level timing must be provided by external circuitry.

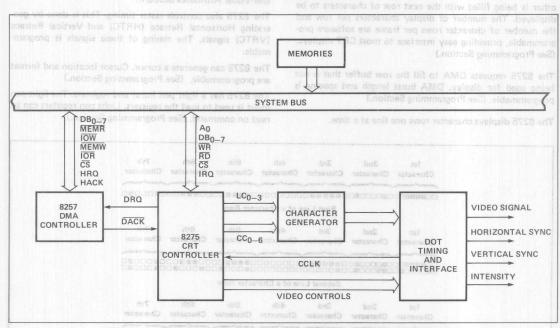

Figure 5. 8275 Systems Block Diagram Showing Systems Operation

Figure 6. Display of a Character Row

mable. (See Programming Section.)

Display characters are retrieved from memory and displayed on a row by row basis. The 8275 has two row buffers. While one row buffer is being used for display, the other is being filled with the next row of characters to be displayed. The number of display characters per row and the number of character rows per frame are software programmable, providing easy interface to most CRT displays. (See Programming Section.)

The 8275 requests DMA to fill the row buffer that is not being used for display. DMA burst length and spacing is programmable. (See Programming Section.)

The 8275 displays character rows one line at a time.

The 8275 provides special Control Codes which can be used to minimize DMA or software overhead. It also provides Visual Attribute Codes to cause special action or symbols on the screen without the use of the character generator (see Visual Attributes Section).

The 8275 also controls raster timing. This is done by generating Horizontal Retrace (HRTC) and Vertical Retrace (VRTC) signals. The timing of these signals is programmable.

The 8275 can generate a cursor. Cursor location and format are programmable. (See Programming Section.)

The 8275 has a light pen input and registers. The light pen input is used to load the registers. Light pen registers can be read on command. (See Programming Section.)

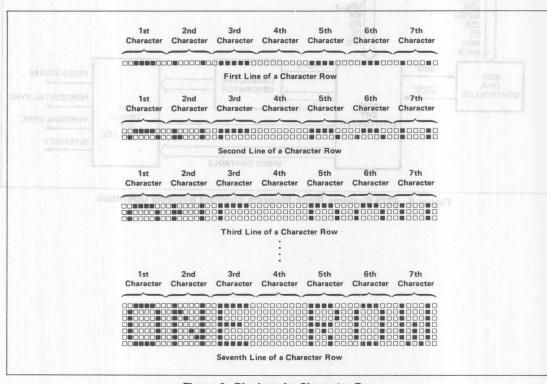

Figure 6. Display of a Character Row

1-359 AFN-00224B

1<sub>9</sub>mi

## **Display Row Buffering**

Before the start of a frame, the 8275 requests DMA and one row buffer is filled with characters.

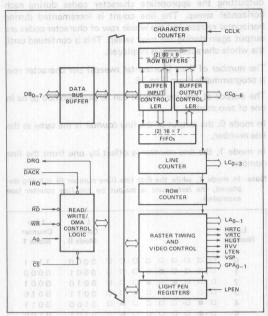

Figure 7. First Row Buffer Filled

When the first horizontal sweep is started, character codes are output to the character generator from the row buffer just filled. Simultaneously, DMA begins filling the other row buffer with the next row of characters.

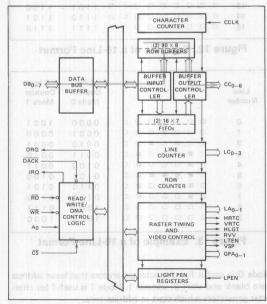

Figure 8. Second Buffer Filled, First Row Displayed

After all the lines of the character row are scanned, the roles of the two row buffers are reversed and the same procedure is followed for the next row.

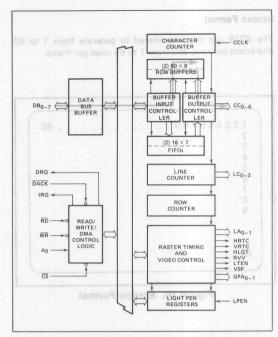

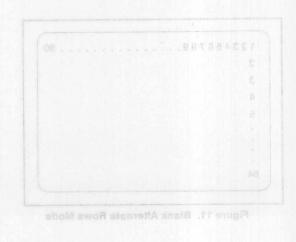

Figure 9. First Buffer Filled with Third Row,
Second Row Displayed

This is repeated until all of the character rows are displayed.

1-360 AFN-00224B

Display Format syon are staffed won owe arts to salor

#### **Screen Format**

The 8275 can be programmed to generate from 1 to 80 characters per row, and from 1 to 64 rows per frame.

After all the lines of the character roy

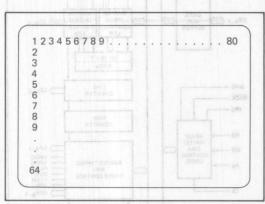

Figure 10. Screen Format

The 8275 can also be programmed to blank alternate rows. In this mode, the first row is displayed, the second blanked, the third displayed, etc. DMA is not requested for the blanked rows.

Figure 11. Blank Alternate Rows Mode

#### **Row Format**

The 8275 is designed to hold the line count stable while outputting the appropriate character codes during each horizontal sweep. The line count is incremented during horizontal retrace and the whole row of character codes are output again during the next sweep. This is continued until the whole character row is displayed.

The number of lines (horizontal sweeps) per character row is programmable from 1 to 16.

The output of the line counter can be programmed to be in one of two modes.

In mode 0, the output of the line *counter* is the same as the line *number*.

In mode 1, the line *counter* is offset by one from the line *number*.

**Note:** In mode 1, while the *first* line (line number 0) is being displayed, the *last* count is output by the line counter (see examples).

Figure 15. Underline in Line Number 7

If the line *number* of the underline is greater than the maximum number of lines, the underline will not appear.

Blanking is accomplished by the VSP (Video Suppression) signal. Underline is accomplished by the LTEN (Light Enable) signal.

#### **Dot Format**

Dot width and character width are dependent upon the external timing and control circuitry.

Dot level timing circuitry should be designed to accept the parallel output of the character generator and shift it out serially at the rate required by the CRT display.

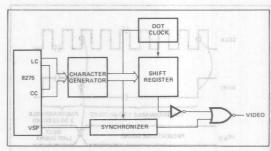

Figure 16. Typical Dot Level Block Diagram

Dot width is a function of dot clock frequency.

Character width is a function of the character generator width.

Horizontal character spacing is a function of the shift register length.

Note: Video control and timing signals must be synchronized with the video signal due to the character generator access delay.

1-362 AFN-00224B

## **Raster Timing**

The character counter is driven by the character clock input (CCLK). It counts out the characters being displayed (programmable from 1 to 80). It then causes the line counter to increment, and it starts counting out the horizontal retrace interval (programmable from 2 to 32). This is constantly repeated.

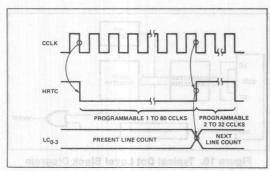

Figure 17. Line Timing

The line counter is driven by the character counter. It is used to generate the line address outputs  $(LC_{0-3})$  for the character generator. After it counts all of the lines in a character row (programmable from 1 to 16), it increments the row counter, and starts over again. (See Character Format Section for detailed description of Line Counter functions)

The row counter is an internal counter driven by the line counter. It controls the functions of the row buffers and counts the number of character rows displayed.

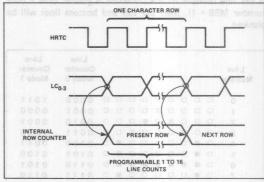

Figure 18. Row Timing

After the row counter counts all of the rows in a frame (programmable from 1 to 64), it starts counting out the vertical retrace interval (programmable from 1 to 4).

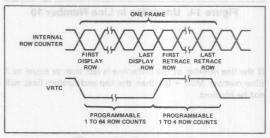

Figure 19. Frame Timing

The Video Suppression Output (VSP) is active during horizontal and vertical retrace intervals.

Dot level timing circuitry must synchronize these outputs with the video signal to the CRT Display.

. . . . . . . .

. . . . . . . .

The 8275 can be programmed to request burst DMA transfers of 1 to 8 characters. The interval between bursts is also programmable (from 0 to 55 character clock periods  $\pm$ 1). This allows the user to tailor his DMA overhead to fit his system needs.

The first DMA request of the frame occurs one *row time* before the end of vertical retrace. DMA requests continue as programmed, until the row buffer is filled. If the row buffer is filled in the middle of a burst, the 8275 terminates the burst and resets the burst counter. No more DMA requests will occur until the *beginning* of the *next* row. At that time, DMA requests are activated as programmed until the other buffer is filled.

The first DMA request for a row will start at the first character clock of the preceding row. If the burst mode is used, the first DMA request may occur a number of character clocks later. This number is equal to the programmed burst space.

If, for any reason, there is a DMA underrun, a flag in the status word will be set.

The 8275 can be programmed to generate an interrupt request at the end of each frame. This can be used to reinitialize the DMA controller. If the 8275 interrupt enable flag is set, an interrupt request will occur at the beginning of the last display row.

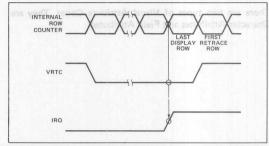

Figure 21. Beginning of Interrupt Request

IRQ will go inactive after the status register is read.

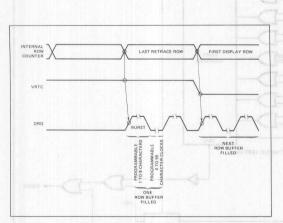

Figure 20. DMA Timing

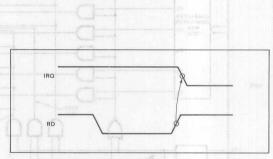

Figure 22. End of Interrupt Request

A reset command will also cause IRQ to go inactive, but this is not recommended during normal service.

Another method of reinitializing the DMA controller is to have the DMA controller itself interrupt on terminal count. With this method, the 8275 interrupt enable flag should not be set.

The DMA controller is typically initialized for the next frame at the end of the current frame.

Note: Upon power-up, the 8275 Interrupt Enable Flag may be set.

As a result, the user's cold start routine should write a reset command to the 8275 before system interrupts are enabled.

# VISUAL ATTRIBUTES AND SPECIAL CODES

The characters processed by the 8275 are 8-bit quantities. The character code outputs provide the character generator with 7 bits of address. The Most Significant Bit is the extra bit and it is used to determine if it is a normal display character (MSB = 0), or if it is a Visual Attribute or Special Code (MSB = 1).

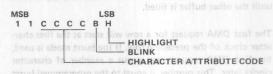

There are two types of Visual Attribute Codes. They are Character Attributes and Field Attributes.

#### **Character Attribute Codes**

Character attribute codes are codes that can be used to generate graphics symbols without the use of a character generator. This is accomplished by selectively activating the Line Attribute outputs  $(LA_{0-1})$ , the Video Suppression output (VSP), and the Light Enable output. The dot level timing circuitry can use these signals to generate the proper symbols.

Character attributes can be programmed to blink or be highlighted individually. Blinking is accomplished with the Video Suppression output (VSP). Blink frequency is equal to the screen refresh frequency divided by 32. Highlighting is accomplished by activating the Highlight output (HGLT).

<sup>\*</sup>Character Attribute Code 1011 is not recommended for normal operation. Since none of the attribute outputs are active, the character Generator will not be disabled, and an indeterminate character will be generated.

Character Attribute Codes 1101, 1110, and 1111 are illegal. Blinking is active when B=1. Highlight is active when H=1.

## **Special Codes**

Four special codes are available to help reduce memory, software, or DMA overhead.

## Special Control Character

S	S	FUNCTION
0	0	End of Row
0	1	End of Row-Stop DMA
1	0	End of Screen
1	1	End of Screen-Stop DMA

The End of Row Code (00) activates VSP and holds it to the end of the line.

The End of Row-Stop DMA Code (01) causes the DMA Control Logic to stop DMA for the rest of the row when it is written into the Row Buffer. It affects the display in the same way as the End of Row Code (00).

The End of Screen Code (10) activates VSP and holds it to the end of the frame

The End of Screen-Stop DMA Code (11) causes the DMA Control Logic to stop DMA for the rest of the frame when it is written into the Row Buffer. It affects the display in the same way as the End of Screen Code (10).

If the Stop DMA feature is not used, all characters after an End of Row character are ignored, except for the End of Screen character, which operates normally. All characters after an End of Screen character are ignored.

Note: If a Stop DMA character is not the last character in a burst or row, DMA is not stopped until after the next character is read. In this situation, a dummy character must be placed in memory after the Stop DMA character.

#### **Field Attributes**

The field attributes are control codes which affect the visual characteristics for a field of characters, starting at the

character following the code up to, and including, the character which precedes the *next* field attribute code, or up to the end of the frame. The field attributes are reset during the vertical retrace interval.

## There are six field attributes:

- Blink Characters following the code are caused to blink by activating the Video Suppression output (VSP). The blink frequency is equal to the screen refresh frequency divided by 32.
- 2. Highlight Characters following the code are caused to be highlighted by activating the Highlight output (HGLT).
- 3. Reverse Video Characters following the code are caused to appear with reverse video by activating the Reverse Video output (RVV).
- Underline Characters following the code are caused to be underlined by activating the Light Enable output (LTEN).
- 5,6. General Purpose There are two additional 8275 outputs which act as general purpose, independently programmable field attributes. GPA<sub>0-1</sub> are active high outputs.

#### **Field Attribute Code**

MSB
1 0 U R G G B H HIGHLIGHT
BLINK
GENERAL PURPOSE
REVERSE VIDEO
UNDERLINE

H = 1 FOR HIGHLIGHTING B = 1 FOR BLINKING R = 1 FOR REVERSE VIDEO U = 1 FOR UNDERLINE GG = GPA<sub>1</sub>, GPA<sub>0</sub>

\*More than one attribute can be enabled at the same time. If the blinking and reverse video attributes are enabled simultaneously, only the reversed characters will blink.

Character Attribute Codes 1101, 1110, and 1111 are flegal.

normal operation. Since none of the attribute outputs en active, the character Generator will not be disabled, and an indeterminate character will be generated.

l<sub>o</sub>lni

The 8275 can be programmed to provide visible or invisible field attribute characters.

If the 8275 is programmed in the visible field attribute mode, all field attributes will occupy a position on the screen. They will appear as blanks caused by activation of the Video Suppression output (VSP). The chosen visual attributes are activated after this blanked character.

Figure 24. Example of the Visible Field Attribute
Mode (Underline Attribute)

If the 8275 is programmed in the invisible field attribute mode, the 8275 FIFO is activated.

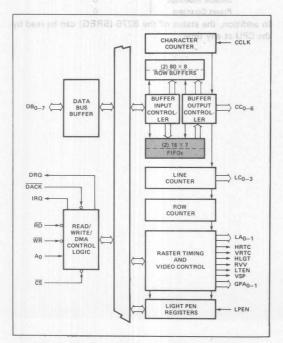

Figure 25. Block Diagram Showing FIFO Activation

Each row buffer has a corresponding FIFO. These FIFOs are 16 characters by 7 bits in size.

When a field attribute is placed in the row buffer during DMA, the buffer input controller recognizes it and places the *next* character in the proper FIFO.

When a field attribute is placed in the Buffer Output Controller during display, it causes the controller to immediately put a character from the FIFO on the Character Code outputs ( $CC_{0-6}$ ). The chosen Visual Attributes are also activated.

Since the FIFO is 16 characters long, no more than 16 field attribute characters may be used per line in this mode. If more are used, a bit in the status word is set and the first characters in the FIFO are written over and lost.

Note: Since the FIFO is 7 bits wide, the MSB of any characters put in it are stripped off. Therefore, a Visual Attribute or Special Code must *not* immediately follow a field attribute code. If this situation does occur, the Visual Attribute or Special Code will be treated as a normal display character.

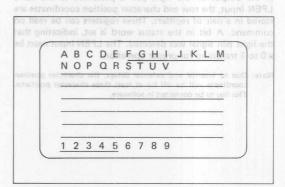

Figure 26. Example of the Invisible Field Attribute Mode (Underline Attribute)

## Field and Character Attribute Interaction

Character Attribute Symbols are affected by the Reverse Video (RVV) and General Purpose ( $\mathsf{GPA}_{0-1}$ ) field attributes. They are not affected by Underline, Blink or Highlight field attributes; however, these characteristics can be programmed *individually* for Character Attribute Symbols.

1-368

## Cursor Timing a polibooquerros a pad reflud wor das3

The cursor location is determined by a cursor row register and a character position register which are loaded by command to the controller. The cursor can be programmed to appear on the display as:

- 1. a blinking underline easily at equality block a negligible
- 2. a blinking reverse video block
- 3. a non-blinking underline most retoristic a translation
- 4. a non-blinking reverse video block

The cursor blinking frequency is equal to the screen refresh frequency divided by 16.

If a non-blinking reverse video *cursor* appears in a non-blinking reverse video *field*, the cursor will appear as a normal video block.

If a non-blinking underline *cursor* appears in a non-blinking underline *field*, the cursor will not be visible.

## Light Pen Detection

A light pen consists of a micro switch and a tiny light sensor. When the light pen is pressed against the CRT screen, the micro switch enables the light sensor. When the raster sweep reaches the light sensor, it triggers the light pen output.

If the output of the light pen is presented to the 8275 LPEN input, the row and character position coordinates are stored in a pair of registers. These registers can be read on command. A bit in the status word is set, indicating that the light pen signal was detected. The LPEN input must be a 0 to 1 transition for proper operation.

Note: Due to internal and external delays, the character position coordinate will be off by at least three character positions. This has to be corrected in software.

## Device Programming of perimerpong ed rea 3353 ed 7

The 8275 has two programming registers, the Command Register (CREG) and the Parameter Register (PREG). It also has a Status Register (SREG). The Command Register can only be written into and the Status Registers can only be read from. They are addressed as follows:

A <sub>0</sub>	OPERATION	REGISTER
0	Read	PREG
0	Write	PREG
1   1	Read   A O	SREG
1	Write	CREG

The 8275 expects to receive a command and a sequence of 0 to 4 parameters, depending on the command. If the proper number of parameter bytes are not received before another command is given, a status flag is set, indicating an improper command.

#### Instruction Set

The 8275 instruction set consists of 8 commands.

COMMAND	NO. OF PARAMETER BYTES
Reset Marian A	nilrebatti e4oM
Start Display	0
Stop Display	0
Read Light Pen	2
Load Cursor	t the 8275 is programmed in t
Enable Interrupt	node, the 8275 FIGO is activated
Disable Interrupt	0
Preset Counters	0

In addition, the status of the 8275 (SREG) can be read by the CPU at any time.

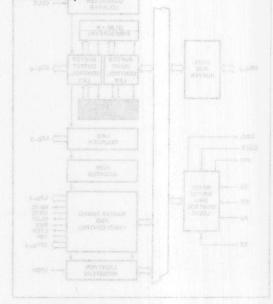

Figure 25. Block Diagram Shewing FIFO

		1	ion	DATA BUS	
	OPERATION	A <sub>0</sub>	DESCRIPTION	MSB	LSB

Action-8275 interrupts are enabled, DMA requests begin, video is enabled, Interrupt Enable and Video Enable status flags are set.

## 3. Stop Display Command:

	OPERATION	Ao	DESCRIPTION	M	SB	DA	ATA	BI	US	L	SB
Command	Write	1	Stop Display	0	1	0	0	0	0	0	0
No	parameters									Т	

Action — Disables video, interrupts remain enabled, HRTC and VRTC continue to run, Video Enable status flag is reset, and the "Start Display" command must be given to re-enable the display.

## 4. Read Light Pen Command

	OPERATION		DESCRIPTION			D	ATA	A BI	US	L	SB
Command	Write	1	Read Light Pen	0	1	1	0	0	0	0	0
Parameters	Read Read	10.5	Char. Number Row Number				siti		n A	ow	)

Action — The 8275 is conditioned to supply the contents of the light pen position registers in the next two read cycles of the parameter register. Status flags are not affected.

Note: Software correction of light pen position is required.

#### 5. Load Cursor Position:

						DA	ATA	BI	JS.		
	OPERATION	A <sub>0</sub>	DESCRIPTION	M	SB					L	SB
Command	Write	1	Load Cursor	1	0	0	0	0	0	0	0
Parameters	Write	0	Char. Number Row Number	100	har.				n R	ow	)

Action — The 8275 is conditioned to place the next two parameter bytes into the cursor position registers. Status flags not affected.

Action - After the reset command is written, DMA re-

# 6. Enable Interrupt Command:

	OPERATION	A <sub>0</sub>	DESCRIPTION	M	SB	D	ATA	ABI	US	L	SB
Command	Write	1	Enable Interrupt	1	0	1	0	0	0	0	0
No	parameters										

Action — The interrupt enable status flag is set and interrupts are enabled.

#### 7. Disable Interrupt Command:

	OPERATION	A <sub>0</sub>	DESCRIPTION	M	SB	D	ATA	B	US	L	SB
Command	Write	1	Disable Interrupt	1	1	0	0	0	0	0	0
No	parameters			0							

Action — Interrupts are disabled and the interrupt enable status flag is reset.

## 8. Preset Counters Command:

	OPERATION	A <sub>0</sub>	DESCRIPTION	M	SB	D	ATA	A B	US	L	SB
Command	Write	1	Preset Counters	1	1	1	0	0	0	0	0
No	parameters										

Action — The internal timing counters are preset, corresponding to a screen display position at the top left corner. Two character clocks are required for this operation. The counters will remain in this state until any other command is given.

This command is useful for system debug and synchronization of clustered CRT displays on a single CPU.

The Intel 8276 Small System CRT Controller is a single chip device intended to interface CRT raster scan displays with Intel microcomputers in minimum device-count systems. Its primary function is to refresh the display by buffering character information from main memory and keeping track of the display position of the screen. The flexibility designed into the 8276 will allow simple interface to almost any raster scan CRT display with a minimum system IC count.

## FUNCTIONAL DESCRIPTION SOME OT STATE OF THE PROPERTY OF THE PR

## **Data Bus Buffer**

This 3-state, bidirectional, 8-bit buffer is used to interface the 8276 to the system Data Bus.

This functional block accepts inputs from the System Control Bus and generates control signals for overall device operation. It contains the Command, Parameter, and Status Registers that store the various control formats for the device functional definition.

C/P	OPERATION	REGISTER
18007	Read R	RESERVED
0	Write	PARAMETER
1	Read	STATUS
office	Write 0	COMMAND

## RD (READ)

A "low" on this input informs the 8276 that the CPU is reading status information from the 8276.

#### WR (WRITE)

A "low" on this input informs the 8276 that the CPU is writing data or control words to the 8276.

## CS (CHIP SELECT)

A "low" on this input selects the 8276 for  $\overline{\text{RD}}$  or  $\overline{\text{WR}}$  of Commands, Status, and Parameters.

#### **BRDY (BUFFER READY)**

A "high" on this output indicates that the 8276 is ready to receive character data.

#### **BS** (BUFFER SELECT)

A "low" on this input enables WR of character data to the 8276 row buffers.

## INT (INTERRUPT)

A "high" on this output informs the CPU that the 8276 needs interrupt service.

C/P	RD	WR	CS	BS	
0	0	1	0	1	Reserved
0	1	0	0	1	Write 8276 Parameter
1	0	1	0	1	Read 8276 Status
1	1	0	0	1	Write 8276 Command
X	1	0	1	0	Write 8276 Row Buffer
X	1	-1	X	X	High Impedance
X	X	X	1	1	High Impedance

## Character Counter MOTTAREGO METRYS

The Character Counter is a programmable counter that is used to determine the number of characters to be displayed per row and the length of the horizontal retrace interval. It is driven by the CCLK (Character Clock) input, which should be derived from the external dot clock.

## **Line Counter**

The Line Counter is a programmable counter that is used to determine the number of horizontal lines (Raster Scans) per character row. Its outputs are used to address the external character generator.

## Row Counter mun ent bins wor reg sretogrado

The Row Counter is a programmable counter that is used to determine the number of character rows to be displayed per frame and length of the vertical retrace interval.

## **Raster Timing and Video Controls**

The Raster Timing circuitry controls the timing of the HRTC (Horizontal Retrace) and VRTC (Vertical Retrace) outputs. The Video Control circuitry controls the generation of HGLT (Highlight), RVV (Reverse Video), LTEN (Light Enable), VSP (Video Suppress), and GPA<sub>0-1</sub> (General Purpose Attribute) outputs.

## **Row Buffers**

The Row Buffers are two 80-character buffers. They are filled from the microcomputer system memory with the character codes to be displayed. While one row buffer is displaying a row of characters, the other is being filled with the next row of characters.

## **Buffer Input/Output Controllers**

The Buffer Input/Output Controllers decode the characters being placed in the row buffers. If the character is a field attribute or special code, they control the appropriate action. (Example: A "Highlight" field attribute will cause the Buffer Output Controller to activate the HGLT output.)

## SYSTEM OPERATION Telauso Telastation

The 8276 is programmable to a large number of different display formats. It provides raster timing, display row buffering, visual attribute decoding and cursor timing.

It is designed to interface with standard character generators for dot matrix decoding. Dot level timing must be provided by external circuitry.

## **General Systems Operational Description**

Display characters are retrieved from memory and displayed on a row-by-row basis. The 8276 has two row buffers. While one row buffer is being used for display, the other is being filled with the next row of characters to be displayed. The number of display characters per row and the number of character rows per frame are software programmable, providing easy interface to most CRT displays. (See Programming Section.)

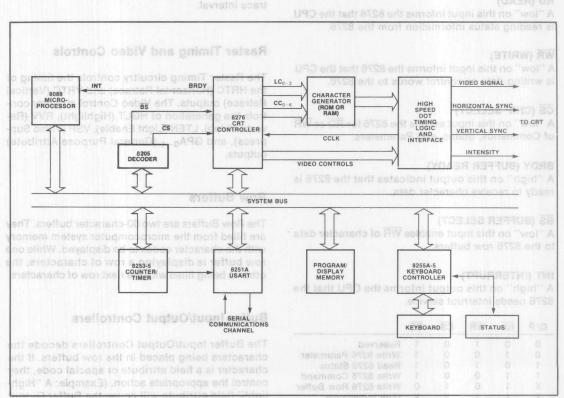

The 8276 uses BRDY to request character data to fill the row buffer that is not being used for display.

The 8276 displays character rows one scan line at a time. The number of scan lines per character row, the underline position, and blanking of top and bottom lines are programmable. (See Programming Section.)

The 8276 provides special Control Codes which can be used to minimize overhead. It also provides Visual Attribute Codes to cause special action on the screen without the use of the character generator. (See Visual Attributes Section.)

The 8276 also controls raster timing. This is done by generating Horizontal Retrace (HRTC) and Vertical Retrace (VRTC) signals. The timing of these signals is also programmable.

The 8276 can generate a cursor. Cursor location and format are programmable. (See Programming Section.)

Liugiuo T. Did en ela Figure 3. CRT System Block Diagram

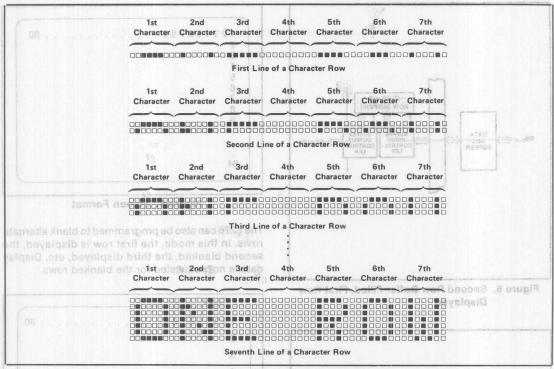

Figure 4. Display Of A Character Row

## **Display Row Buffering**

Before the start of a frame, the 8276 uses BRDY and BS to fill one row buffer with characters.

When the first horizontal sweep is started, character codes are output to the character generator from the row buffer just filled. Simultaneously, the other row buffer is filled with the next row of characters.

After all the lines of the character row are scanned, the buffers are swapped and the same procedure is followed for the next row.

This process is repeated until all of the character rows are displayed.

Row Buffering allows the CPU access to the display memory at all times except during Buffer Loading (about 25%). This compares favorably to alternative approaches which restrict CPU access to the display memory to occur only during horizontal and vertical retrace intervals (80% of the bus time is used to refresh the display.)

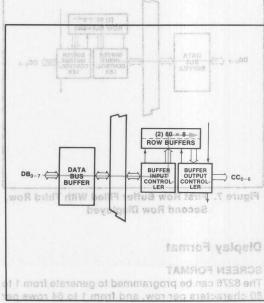

Figure 5. First Row Buffer Filled

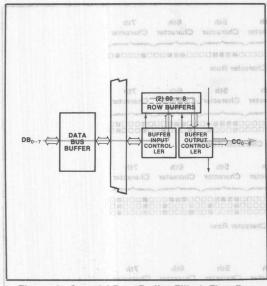

Figure 6. Second Row Buffer Filled, First Row Displayed

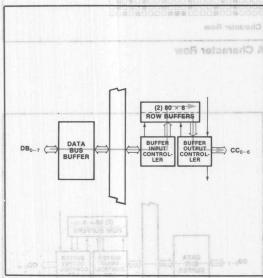

Figure 7. First Row Buffer Filled With Third Row, Second Row Displayed

## **Display Format**

## **SCREEN FORMAT**

The 8276 can be programmed to generate from 1 to 80 characters per row, and from 1 to 64 rows per frame.

Figure 8. Screen Format

The 8276 can also be programmed to blank alternate rows. In this mode, the first row is displayed, the second blanked, the third displayed, etc. Display data is not requested for the blanked rows.

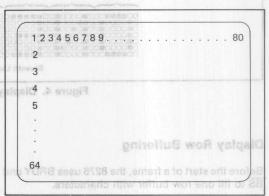

Figure 9. Blank Alternate Rows Mode

## **ROW FORMAT**

The 8276 is designed to hold the line count stable while outputting the appropriate character codes during each horizontal sweep. The line count is incremented during horizontal retrace and the whole row of character codes are output again during the next sweep. This is continued until the entire character row is displayed.

The number of lines (horizontal sweeps) per character row is programmable from 1 to 16.

The output of the line counter can be programmed to be in one of two modes.

In mode 0, the output of the line *counter* is the same as the line *number*.

In mode 1, the line counter is offset by one from the line number, no searchs end out extended to be succeed to be a first out to be a fir

Note: In mode 1, while the first line (line number 0) is being displayed, the last count is output by the line counter (see examples).

Line lumber									Line Counter Mode 0	
0					0				0000	111
1									0001	000
2									0010	000
3							0		0011	001

9			0	0	0	0		1001	1000

Figure 11. Example of a 10-Line Format

Mode 0 is useful for character generators that leave address zero blank and start at address 1. Mode 1 is useful for character generators which start at address zero.

Underline placement is also programmable (from line *number* 0 to 15). This is independent of the line *counter* mode.

If the line *number* of the underline is greater than 7 (line *number* MSB = 1), then the top and bottom lines will be blanked.

Line Number									Counter Mode 0	Counter Mode 1
0	0								0000	1011
1									0001	0000

dina7anoo	a.Fa					Р.	(88)	0111	0110
									.beised
	Top and Bottom Lines are not Blanked								

Figure 13. Underline in Line Number 7

If the line *number* of the underline is greater than the maximum number of lines, the underline will not appear.

Blanking is accomplished by the VSP (Video Suppression) signal. Underline is accomplished by the LTEN (Light Enable) signal.

#### If the line number of the underline is TAMROT TOO

Dot width and character width are dependent upon the external timing and control circuitry.

Dot level timing circuitry should be designed to accept the parallel output of the character generator and shift it out serially at the rate required by the CRT display.

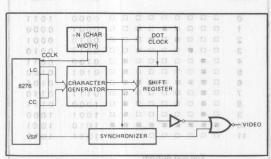

Figure 14. Typical Dot Level Block Diagram

Dot width is a function of dot clock frequency.

Character width is a function of the character generator width, in page and to redmun end to

Horizontal character spacing is a function of the shift register length.

Note: Video control and timing signals must be synchronized with the video signal due to the character generator access delay.

## **Raster Timing**

The character counter is driven by the character clock input (CCLK). It counts out the characters being displayed (programmable from 1 to 80). It then causes the line counter to increment, and it starts counting out the horizontal retrace interval (programmable from 2 to 32). This process is constantly repeated.

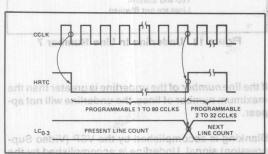

Figure 15. Line Timing 3 (doi.) M3T.

The line counter is driven by the character counter. It is used to generate the line address outputs ( $LC_{0-3}$ ) for the character generator. After it counts all of the lines in a character row (programmable from 1 to 16), it increments the row counter, and starts over again. (See Character Format Section for detailed description of Line Counter functions.)

The row counter is an internal counter driven by the line counter. It controls the functions of the row buffers and counts the number of character rows displayed.

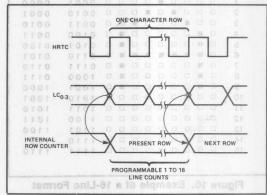

Figure 16. Row Timing

After the row counter counts all of the rows in a frame (programmable from 1 to 64), it starts counting out the vertical retrace interval (programmable from 1 to 4).

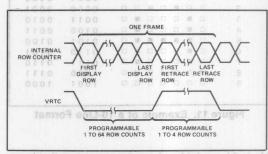

Figure 17. Frame Timing

The Video Suppression Output (VSP) is active during horizontal and vertical retrace intervals.

Dot level timing circuitry must synchronize these outputs with the video signal to the CRT Display.

## **Interrupt Timing**

The 8276 can be programmed to generate an interrupt request at the end of each frame. If the 8276 interrupt enable flag is set, an interrupt request will occur at the beginning of the last display row.

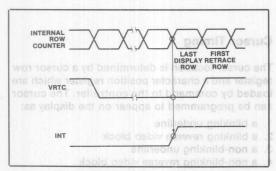

Figure 18. Beginning of Interrupt

INT will go inactive after the status register is read.

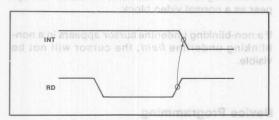

Figure 19. End of Interrupt

A reset command will also cause INT to go inactive, but this is not recommended during normal service.

Note: Upon power-up, the 8276 Interrupt Enable Flag may be set. As a result, the user's cold start routine should write a reset command to the 8276 before system interrupts are enabled.

# VISUAL ATTRIBUTES AND SPECIAL CODES

The characters processed by the 8276 are 8-bit quantities. The character code outputs provide the character generator with 7 bits of address. The Most Significant Bit is the extra bit and it is used to determine if it is a normal display character (MSB = 0), or if it is a Field Attribute or Special Code (MSB = 1).

## Special Codes g of bernmangong ed nac 8728 and

Four special codes are available to help reduce bus usage. And to not substant yet because a read as used

## SPECIAL CONTROL CHARACTER

SB 1	enon eni	e are six field attrioure agu
		SPECIAL CONTROL CO
		pression output (VSP). The blint equal to the NOITONUT elresh frequency
	0 0	End of Row SE yd
918	0 1	End of Row-Stop Buffer Loading
Hgh-	1 0	End of Screen inpliced of becuse

The End of Row Code (00) activates VSP and holds it to the end of the line.

The End of Row-Stop Buffer Loading (BRDY) Code (01) causes the Buffer Loading Control Logic to stop buffer loading for the rest of the row upon being written into the Row Buffer. It affects the display in the same way as the End of Row Code (00).

The End of Screen Code (10) activates VSP and holds it to the end of the frame.

The End of Screen-Stop Buffer Loading (BRDY) Code (11) causes the Row Buffer Control Logic to stop buffer loading for the rest of the frame upon being written. It affects the display in the same way as the End of Screen Code (10).

If the Stop Buffer Loading feature is not used, all characters after an End of Row character are ignored, except for the End of Screen character, which operates normally. All characters after an End of Screen character are ignored.

Note: If a Stop Buffer Loading is not the last character in a row, Buffer Loading is not stopped until after the next character is read. In this situation, a dummy character must be placed in memory after the Stop Buffer Loading character.

#### **Field Attributes**

The field attributes are control codes which affect the visual characteristics for a field of characters, starting at the character following the code up to, and including, the character which precedes the next field attribute code, or up to the end of the frame. The field attributes are reset during the vertical retrace interval

The 8276 can be programmed to provide visible field attribute characters; all field attribute codes will occupy a position on the screen. These codes will appear as blanks caused by activation of the Video Suppression output (VSP). The chosen visual attributes are activated after this blanked character.

There are six field attributes:

- 1. Blink-Characters following the code are caused to blink by activating the Video Suppression output (VSP). The blink frequency is equal to the screen refresh frequency divided by 32.
- 2. Highlight-Characters following the code are caused to be highlighted by activating the Highlight output (HGLT).
- 3. Reverse Video Characters following the code are caused to appear with reverse video by activating the Reverse Video output (RVV).
- 4. Underline—Characters following the code are caused to be underlined by activating the Light of Enable output (LTEN): of reffue and seauso (10)
- 5,6. General Purpose—There are two additional 8276 outputs which act as general purpose, independently programmable field attributes.  $GPA_{0-1}$  are active high outputs.

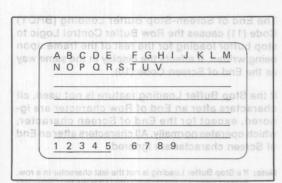

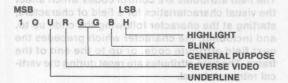

Figure 20. Example of a Visible Field Attribute reference (Underline Attribute)

### FIELD ATTRIBUTE CODE

H = 1 FOR HIGHLIGHTING

B = 1 FOR BLINKING

R = 1 FOR REVERSE VIDEO

U = 1 FOR UNDERLINE Demanapora ed nac 8758 edT

GG = GPA1, GPA0 STI doss to bus ent is temper tour interrupt enable flag is set, an interrupt re

Note: More than one attribute can be enabled at the same time. If the blinking and reverse video attributes are enabled simultaneously, only the reversed characters will blink.

### **Cursor Timing**

The cursor location is determined by a cursor row register and a character position register which are loaded by command to the controller. The cursor can be programmed to appear on the display as:

- 1. a blinking underline
- 2. a blinking reverse video block
- 3. a non-blinking underline
- 4. a non-blinking reverse video block

The cursor blinking frequency is equal to the screen refresh frequency divided by 16.

If a non-blinking reverse video cursor appears in a non-blinking reverse video field, the cursor will appear as a normal video block.

If a non-blinking underline cursor appears in a nonblinking underline field, the cursor will not be visible.

### **Device Programming**

The 8276 has two programming registers, the Command Register and the Parameter Register. It also has a Status Register. The Command Register can only be written into and the Status Register can only be read from. They are addressed as follows:

C/P	OPERATION	REGISTER		
0	Read	Reserved		
0	Write	Parameter		
1	Read	Status		
1	Write 83	Command		

The 8276 expects to receive a command and a sequence of 0 to 4 parameters, depending on the command. If the proper number of parameter bytes are not received before another command is given, a status flag is set, indicating an improper command.

# Instruction Set MOD TRUBBETH BJBASIC .8

The 8276 instruction set consists of 7 commands.

COMMAND	NO. OF PARAMETER BYTES
Resetti erit bns	citon-Interrutts are disabled
Start Display	nable status flog is reset.
Stop Display	0
Load Cursor	PRESET COUNTERS COMM
Enable Interrupt	PRESET COUNTERS COMMI
Disable Interrupt	0
Preset Counters	Commend Write 1 Press County

In addition, the status of the 8276 can be read by the CPU at any time.

# 1. RESET COMMAND sib neeros s of phionogeomos

of the frame

	OPERATION	C/P	DESCRIPTION	DATA BUS MSB LSB

Note: uuuu MSB determines blanking of top and bottom lines (1 = blanked, 0 = not blanked).

### 2. START DISPLAY COMMAND

	OPERATION	C/P	DESCRIPTION	M	SB		ATA	B	US	LS	SB
Command	Write	1	Start Display	0	0	1	0	0	0	0	0
No p	arameters										

Action—8276 interrupts are enabled, BRDY goes active, video is enabled, Interrupt Enable and Video Enable status flags are set.

### 3. STOP DISPLAY COMMAND

	OPERATION	C/P	DESCRIPTION	м	SB	DA	ATA	В	US	LS	SB
Command	Write	1	Stop Display	0	1	0	0	0	0	0	0

Action—Disables video, interrupts remain enabled, HRTC and VRTC continue to run, Video Enable status flag is reset, and the "Start Display" command must be given to reenable the display.

### 4. LOAD CURSOR POSITION

	OPERATION	C/P	DESCRIPTION	MSB LSB
Command	Write 8	1	Load Cursor	10000000
Parameters	Write Write	0	Char. Number Row Number	(Char. Position in Row) (Row Number)

Action—The 8276 is conditioned to place the next two parameter bytes into the cursor position registers. Status flag not affected.

### 5. ENABLE INTERRUPT COMMAND

	OPERATION	C/P	M	SB	D	ATA	В	US		SB	
Command	Write	09.8	Enable Interrupt	1	0	1	0	0	0	0	C
No p	parameters	Saint .			9			ñ	in its	-	Ī

Action—The interrupt enable flag is set and interrupts are enabled.

### 6. DISABLE INTERRUPT COMMAND

shaama	OPERATION	C/P	DESCRIPTION	M	SB		ATA	B	US	1	SB
Command	Write	1	Disable Interrupt	1	1	0	0	0	0	0	0
No p	parameters		in nu				24	253	64		

Action—Interrupts are disabled and the interrupt enable status flag is reset.

### 7. PRESET COUNTERS COMMAND

	OPERATION	C/P	DESCRIPTION	M	SB	D	ATA	B	US.	LS	SB
Command	Write	1	Preset Counters	1	1	1	0	0	0	0	0
No p	arameters	tres	and the protect	0	a.	1.9	6	0	41		10

Action—The internal timing counters are preset, corresponding to a screen display position at the top left corner. Two character clocks are required for this operation. The counters will remain in this state until any other command is given.

This command is useful for system debug and synchronization of clustered CRT displays on a single CPU.

# Status Flags | Drammoo lear ent rettA-noito

and the ATC and	OPERATION	C/P	DESCRIPTION	DATA BUS MSB LSB
Command	Read	ad f	Status Word	0 IE IR X IC VE BU X

- IE (Interrupt Enable) Set or reset by command.

  It enables vertical retrace interrupt. It is automatically set by a "Start Display" command and reset with the "Reset" command.
- IR (Interrupt Request) This flag is set at the beginning of display of the last row of the frame if the interrupt enable flag is set. It is reset after a status read operation.
- IC (Improper Command) This flag is set when a command parameter string is too long or too short. The flag is automatically reset after a status read.
- VE (Video Enable) This flag indicates that video operation of the CRT is enabled. This flag is set on a "Start Display" command, and reset on a "Stop Display" or "Reset" command.
- BU (Buffer Underrun) This flag is set whenever a Row Buffer is not filled with character data in time for a buffer swap required by the display. Upon activation of this bit, buffer loading ceases, and the screen is blanked until after the vertical retrace interval.

- m Interrupt Output on Key Entry

The Intel® 8279 is a general purpose programmable keyboard and display I/O interface device designed for use with Intel® microprocessors. The keyboard portion can provide a scanned interface to a 64-contact key matrix. The keyboard portion will also interface to an array of sensors or a strobed interface keyboard, such as the hall effect and ferrite variety. Key depressions can be 2-key lockout or N-key rollover. Keyboard entries are debounced and strobed in an 8-character FIFO. If more than 8 characters are entered, overrun status is set. Key entries set the interrupt output line to the CPU.

The display portion provides a scanned display interface for LED, incandescent, and other popular display technologies. Both numeric and alphanumeric segment displays may be used as well as simple indicators. The 8279 has 16X8 display RAM which can be organized into dual 16X4. The RAM can be loaded or interrogated by the CPU. Both right entry, calculator and left entry typewriter display formats are possible. Both read and write of the display RAM can be done with auto-increment of the display RAM address.

SHIFT SHOP MAN	d in	Shift: The shift input status is stored along with the key position on key closure in the Scanned Keyboard modes. It has an active internal pullup to keep it high until a switch closure pulls it low.					
	1 (siqe hid- mnoi	Control/Strobed Input Mode: For keyboard modes this line is used as a control input and stored like status on a key closure. The line is also the strobe line that enters the data into the FIFO in the Strobed Input mode.  (Rising Edge). It has an active internal pullup to keep it high until a switch closure pulls it low.					
OUT A <sub>0</sub> -OUT A <sub>3</sub> OUT B <sub>0</sub> -OUT B <sub>3</sub>	4 4 1m b 1sib 1	Outputs: These two ports are the outputs for the 16 x 4 display refresh registers. The data from these outputs is synchronized to the scan lines (SL <sub>0</sub> –SL <sub>3</sub> ) for multiplexed digit displays. The two 4 bit ports may be blanked independently. These two ports may also be considered as one 8-bit port.					
BD	1	Blank Display: This output is used to blank the display during digit switching or by a display blanking command.					

### **FUNCTIONAL DESCRIPTION**

Since data input and display are an integral part of many microprocessor designs, the system designer needs an interface that can control these functions without placing a large load on the CPU. The 8279 provides this function for 8-bit microprocessors.

The 8279 has two sections: keyboard and display. The keyboard section can interface to regular typewriter style keyboards or random toggle or thumb switches. The display section drives alphanumeric displays or a bank of indicator lights. Thus the CPU is relieved from scanning the keyboard or refreshing the display.

The 8279 is designed to directly connect to the microprocessor bus. The CPU can program all operating modes for the 8279. These modes include:

manpalG koel6

### input modes

- Scanned Keyboard with encoded (8 x 8 key keyboard) or decoded (4 x 8 key keyboard) scan lines. A key depression generates a 6-bit encoding of key position. Position and shift and control status are stored in the FIFO. Keys are automatically debounced with 2-key lockout or N-key rollover.
- Scanned Sensor Matrix with encoded (8 x 8 matrix switches) or decoded (4 x 8 matrix switches) scan lines.
   Key status (open or closed) stored in RAM addressable by CPU.
- Strobed Input Data on return lines during control line strobe is transferred to FIFO.

### Output Modes at bedara lorded

- 8 or 16 character multiplexed displays that can be organized as dual 4-bit or single 8-bit (B<sub>0</sub> = D<sub>0</sub>, A<sub>3</sub> = D<sub>7</sub>).
- · Right entry or left entry display formats.

Other features of the 8279 include:

- · Mode programming from the CPU.
- Clock Prescaler
- Interrupt output to signal CPU when there is keyboard or sensor data available.
- An 8 byte FIFO to store keyboard information.
- 16 byte internal Display RAM for display refresh. This RAM can also be read by the CPU.

### PRINCIPLES OF OPERATION

The following is a description of the major elements of the 8279 Programmable Keyboard/Display interface device. Refer to the block diagram in Figure 3.

### I/O Control and Data Buffers

The I/O control section uses the  $\overline{CS}$ ,  $A_0$ ,  $\overline{RD}$  and  $\overline{WR}$  lines to control data flow to and from the various internal registers and buffers. All data flow to and from the 8279 is enabled by  $\overline{CS}$ . The character of the information, given or desired by the CPU, is identified by  $A_0$ . A logic one means the information is a command or status. A logic zero means the information is data.  $\overline{RD}$  and  $\overline{WR}$  determine the direction of data flow through the Data Buffers. The Data Buffers are bi-directional buffers that connect the internal bus to the external bus. When the chip is not selected ( $\overline{CS}$  = 1), the devices are in a high impedance state. The drivers input during  $\overline{WR} \bullet \overline{CS}$  and output during  $\overline{RD} \bullet \overline{CS}$ .

### **Control and Timing Registers and Timing Control**

These registers store the keyboard and display modes and other operating conditions programmed by the CPU. The modes are programmed by presenting the proper command on the data lines with  $A_0 = 1$  and then sending a  $\overline{WR}$ . The command is latched on the rising edge of  $\overline{WR}$ .

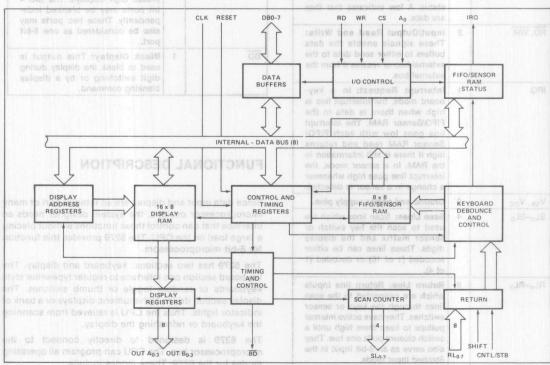

Figure 3. Internal Block Diagram

The command is then decoded and the appropriate function is set. The timing control contains the basic timing counter chain. The first counter is a  $\div$  N prescaler that can be programmed to yield an internal frequency of 100 kHz which gives a 5.1 ms keyboard scan time and a 10.3 ms debounce time. The other counters divide down the basic internal frequency to provide the proper key scan, row scan, keyboard matrix scan, and display scan times.

### Scan Counter on organ os xelf = BA

The scan counter has two modes. In the encoded mode, the counter provides a binary count that must be externally decoded to provide the scan lines for the keyboard and display. In the decoded mode, the scan counter decodes the least significant 2 bits and provides a decoded 1 of 4 scan. Note than when the keyboard is in decoded scan, so is the display. This means that only the first 4 characters in the Display RAM are displayed.

In the encoded mode, the scan lines are active high outputs. In the decoded mode, the scan lines are active low outputs.

# Return Buffers and Keyboard Debounce and Control

The 8 return lines are buffered and latched by the Return Buffers. In the keyboard mode, these lines are scanned, looking for key closures in that row. If the debounce circuit detects a closed switch, it waits about 10 msec to check if the switch remains closed. If it does, the address of the switch in the matrix plus the status of SHIFT and CONTROL are transferred to the FIFO. In the scanned Sensor Matrix modes, the contents of the return lines is directly transferred to the corresponding row of the Sensor RAM (FIFO) each key scan time. In Strobed Input mode, the contents of the return lines are transferred to the FIFO on the rising edge of the CNTL/STB line pulse.

# FIFO/Sensor RAM and Status

This block is a dual function 8 x 8 RAM. In Keyboard or Strobed Input modes, it is a FIFO. Each new entry is written into successive RAM positions and each is then read in order of entry. FIFO status keeps track of the number of characters in the FIFO and whether it is full or empty. Too many reads or writes will be recognized as an error. The status can be read by an  $\overline{\text{RD}}$  with  $\overline{\text{CS}}$  low and  $A_0$  high. The status logic also provides an IRQ signal when the FIFO is not empty. In Scanned Sensor Matrix mode, the memory is a Sensor RAM. Each row of the Sensor RAM is loaded with the status of the corresponding row of sensor in the sensor matrix. In this mode, IRQ is high if a change in a sensor is detected.

### Display Address Registers and Display RAM

The Display Address Registers hold the address of the word currently being written or read by the CPU and the two 4-bit nibbles being displayed. The read/write addresses are programmed by CPU command. They also can be set to auto increment after each read or write. The Display RAM can be directly read by the CPU after the correct mode and address is set. The addresses for the A and B nibbles are automatically updated by the 8279 to match data entry by the CPU. The A and B nibbles can be entered independently or as one word, according to the mode that is set by the CPU. Data entry to the display can be set to either left or right entry. See Interface Considerations for details.

### SOFTWARE OPERATION

### 8279 commands

The following commands program the 8279 operating modes. The commands are sent on the Data Bus with  $\overline{CS}$  low and  $A_0$  high and are loaded to the 8279 on the rising edge of  $\overline{WR}$ .

# Keyboard/Display Mode Set

	MSI	3							
Code:	0	0	0	D	D	K	K	K	

Where DD is the Display Mode and KKK is the Keyboard Mode.

### DD

- 0 0 8 8-bit character display Left entry
- 0 1 16 8-bit character display Left entry\* 388 1918
- 1 0 8 8-bit character display Right entry
- 1 1 16 8-bit character display Right entry

For description of right and left entry, see Interface Considerations. Note that when decoded scan is set in keyboard mode, the display is reduced to 4 characters independent of display mode set.

### KKK

- 0 0 0 Encoded Scan Keyboard 2 Key Lockout\*
- 0 0 1 Decoded Scan Keyboard 2-Key Lockout
- 0 1 0 Encoded Scan Keyboard N-Key Rollover
- 0 1 1 Decoded Scan Keyboard N-Key Rollover
- 1 0 0 Encoded Scan Sensor Matrix
- 1 0 1 Decoded Scan Sensor Matrix
- 1 1 0 Strobed Input, Encoded Display Scan
- 1 1 1 Strobed Input, Decoded Display Scan comeno

### Program Clock

All timing and multiplexing signals for the 8279 are generated by an internal prescaler. This prescaler divides the external clock (pin 3) by a programmable integer. Bits PPPPP determine the value of this integer which ranges from 2 to 31. Choosing a divisor that yields 100 kHz will give the specified scan and debounce times. For instance, if Pin 3 of the 8279 is being clocked by a 2 MHz signal, PPPPP should be set to 10100 to divide the clock by 20 to yield the proper 100 kHz operating frequency.

### Read FIFO/Sensor RAM

Code:	0	1	0	Al	X	A	A	A	X = Don't Care
									the FIFO/Sensor

\*Default after reset.

board Mode, the Auto-Increment flag (AI) and the RAM address bits (AAA) are irrelevant. The 8279 will automatically drive the data bus for each subsequent read ( $A_0=0$ ) in the same sequence in which the data first entered the FIFO. All subsequent reads will be from the FIFO until another command is issued.

In the Sensor Matrix Mode, the RAM address bits AAA select one of the 8 rows of the Sensor RAM. If the AI flag is set (AI = 1), each successive read will be from the subsequent row of the sensor RAM.

### Read Display RAM

Code: 0 1 1 Al A A A A

The CPU sets up the 8279 for a read of the Display RAM by first writing this command. The address bits AAAA select one of the 16 rows of the Display RAM. If the AI flag is set (AI = 1), this row address will be incremented after each following read *or write* to the Display RAM. Since the same counter is used for both reading and writing, this command sets the next read *or write* address and the sense of the Auto-Increment mode for both operations.

### Write Display RAM

Code: 1 0 0 Al A A A A

The CPU sets up the 8279 for a write to the Display RAM by first writing this command. After writing the command with  $A_0=1$ , all subsequent writes with  $A_0=0$  will be to the Display RAM. The addressing and AutoIncrement functions are identical to those for the Read Display RAM. However, this command does not affect the source of subsequent Data Reads; the CPU will read from whichever RAM (Display or FIFO/Sensor) which was last specified. If, indeed, the Display RAM was last specified, the Write Display RAM will, nevertheless, change the next Read location.

### Display Write Inhibit/Blanking

A B A B Code: 1 0 1 X IW IW BL BL

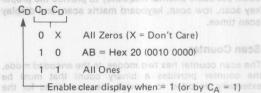

The IW Bits can be used to mask nibble A and nibble B in applications requiring separate 4-bit display ports. By setting the IW flag (IW = 1) for one of the ports, the port becomes marked so that entries to the Display RAM from the CPU do not affect that port. Thus, if each nibble is input to a BCD decoder, the CPU may write a digit to the Display RAM without affecting the other digit being displayed. It is important to note that bit  $B_0$  corresponds to bit  $D_0$  on the CPU bus, and that bit  $A_3$  corresponds to bit  $D_7$ .

If the user wishes to blank the display, the BL flags are available for each nibble. The last Clear command issued determines the code to be used as a "blank." This code defaults to all zeros after a reset. Note that both BL flags must be set to blank a display formatted with a single 8-bit port.

### Clear

Code: 1 1 0 C<sub>D</sub> C<sub>D</sub> C<sub>D</sub> C<sub>F</sub> C<sub>A</sub>

The C<sub>D</sub> bits are available in this command to clear all rows of the Display RAM to a selectable blanking code as follows:

During the time the Display RAM is being cleared ( $\sim$ 160  $\mu$ s), it may not be written to. The most significant bit of the FIFO status word is set during this time. When the Display RAM becomes available again, it automatically resets

If the  $C_F$  bit is asserted ( $C_F$ =1), the FIFO status is cleared and the interrupt output line is reset. Also, the Sensor RAM pointer is set to row 0.

 $C_A$ , the Clear All bit, has the combined effect of  $C_D$  and  $C_F$ ; it uses the  $C_D$  clearing code on the Display RAM and also clears FIFO status. Furthermore, it resynchronizes the internal timing chain.

# End Interrupt/Error Mode Set

Code: 1 1 1 E X X X X X = Don't care.

For the sensor matrix modes this command lowers the IRQ line and enables further writing into RAM. (The IRQ line would have been raised upon the detection of a change in a sensor value. This would have also inhibited further writing into the RAM until reset).

For the N-key rollover mode — if the E bit is programmed to "1" the chip will operate in the special Error mode. (For further details, see Interface Considerations Section.)

### Status Word

The status word contains the FIFO status, error, and display unavailable signals. This word is read by the CPU when  $A_0$  is high and  $\overline{CS}$  and  $\overline{RD}$  are low. See Interface Considerations for more detail on status word.

### **Data Read**

Data is read when A<sub>0</sub>,  $\overline{CS}$  and  $\overline{RD}$  are all low. The source of the data is specified by the Read FIFO or Read Display commands. The trailing edge of  $\overline{RD}$  will cause the address of the RAM being read to be incremented if the Auto-Increment flag is set. FIFO reads always increment (if no error occurs) independent of AI.

### Data Write

Data that is written with  $A_0$ ,  $\overline{CS}$  and  $\overline{WR}$  low is always written to the Display RAM. The address is specified by the latest Read Display or Write Display command. Auto-Incrementing on the rising edge of  $\overline{WR}$  occurs if AI set by the latest display command.

### INTERFACE CONSIDERATIONS

### Scanned Keyboard Mode, 2-Key Lockout

There are three possible combinations of conditions that can occur during debounce scanning. When a key is depressed, the debounce logic is set. Other depressed keys are looked for during the next two scans. If none are encountered, it is a single key depression and the key position is entered into the FIFO along with the status of CNTL and SHIFT lines. If the FIFO was empty, IRQ will be set to signal the CPU that there is an entry in the FIFO. If the FIFO was full, the key will not be entered and the error flag will be set. If another closed switch is encountered, no entry to the FIFO can occur. If all other keys are released before this one, then it will be entered to the FIFO. If this key is released before any other, it will be entirely ignored. A key is entered to the FIFO only once per depression, no matter how many keys were pressed along with it or in what order they were released. If two keys are depressed within the debounce cycle, it is a simultaneous depression. Neither key will be recognized until one key remains depressed alone. The last key will be treated as a single key depression.

### Scanned Keyboard Mode, N-Key Rollover

With N-key Rollover each key depression is treated independently from all others. When a key is depressed, the debounce circuit waits 2 keyboard scans and then checks to see if the key is still down. If it is, the key is entered into the FIFO. Any number of keys can be depressed and another can be recognized and entered into the FIFO. If a simultaneous depression occurs, the keys are recognized and entered according to the order the keyboard scan found them.

### Scanned Keyboard — Special Error Modes

For N-key rollover mode the user can program a special error mode. This is done by the "End Interrupt/Error Mode Set" command. The debounce cycle and key-validity check are as in normal N-key mode. If during a single debounce cycle, two keys are found depressed, this is considered a simultaneous multiple depression, and sets an error flag. This flag will prevent any further writing into the FIFO and will set interrupt (if not yet set). The error flag could be read in this mode by reading the FIFO STATUS word. (See "FIFO STATUS" for further details.) The error flag is reset by sending the normal CLEAR command with CF = 1.

### Sensor Matrix Mode

In Sensor Matrix mode, the debounce logic is inhibited. The status of the sensor switch is inputted directly to the Sensor RAM. In this way the Sensor RAM keeps an image of the state of the switches in the sensor matrix. Although debouncing is not provided, this mode has the advantage that the CPU knows how long the sensor was closed and when it was released. A keyboard mode can only indicate a validated closure. To make the software easier, the designer should functionally group the sensors by row since this is the format in which the CPU will read them. The IRQ line goes high if any sensor value change is detected at the end of a sensor matrix scan. The IRQ line is

cleared by the first data read operation if the Auto-

Increment flag is set to zero, or by the End Interrupt command if the Auto-Increment flag is set to one.

Note: Multiple changes in the matrix Addressed by  $(SL_{0-3} = 0)$  may cause multiple interrupts.  $(SL_{0} = 0)$  in the Decoded Mode). Reset may cause the 8279 to see multiple changes.

### **Data Format**

In the Scanned Keyboard mode, the character entered into the FIFO corresponds to the position of the switch in the keyboard plus the status of the CNTL and SHIFT lines (non-inverted). CNTL is the MSB of the character and SHIFT is the next most significant bit. The next three bits are from the scan counter and indicate the row the key was found in. The last three bits are from the column counter and indicate to which return line the key was connected.

In Sensor Matrix mode, the data on the return lines is entered directly in the row of the Sensor RAM that corresponds to the row in the matrix being scanned. Therefore, each switch postion maps directly to a Sensor RAM position. The SHIFT and CNTL inputs are ignored in this mode. Note that switches are not necessarily the only thing that can be connected to the return lines in this mode. Any logic that can be triggered by the scan lines can enter data to the return line inputs. Eight multiplexed input ports could be tied to the return lines and scanned by the 8279.

In Strobed Input mode, the data is also entered to the FIFO from the return lines. The data is entered by the rising edge of a CNTL/STB line pulse. Data can come from another encoded keyboard or simple switch matrix. The return lines can also be used as a general purpose strobed input.

### Display

### Left Entry

Left Entry mode is the simplest display format in that each display position directly corresponds to a byte (or nibble) in the Display RAM. Address 0 in the RAM is the left-most display character and address 15 (or address 7 in 8 character display) is the right most display character. Entering characters from position zero causes the display to fill from the left. The 17th (9th) character is entered back in the left most position and filling again proceeds from there

	0 1	14 15
2nd entry	1 2 1871 9	ti ni est ni
	8279 to 1eeonu	ed 14 15
16th entry	1 2	15 16
	mode, tite oha	
17th entry	17 2	15 16
	is the MSB <sub>0</sub> of	
18th entry	17 18	15 16

LEFT ENTRY MODE
(AUTO INCREMENT)

### **Right Entry**

Right entry is the method used by most electronic calculators. The first entry is placed in the right most display character. The next entry is also placed in the right most character after the display is shifted left one character. The left most character is shifted off the end and is lost.

	2000	14 15 0 ← Display
1st entry	Fught of Vic	1 RAM Address
	2 3 1 0	thing that cant bo cernected
2nd entry	iggeren u e inauss Ei	yn A ebom
	3 4	input ports core of terior dito the r
3rd entry		1 2 3
	0 1	13 14 15
	-	
16th entry	1 2	14 15 16
	1 2	14 15 0 on bedout of
17th entry		from the ret. 15 16 17 the dat
	2 3	edge of a CNTL/STE line pu
18th entry	3 4	26 bear 16 17 18 5 and muler
		inoni

Note that now the display position and register address do not correspond. Consequently, entering a character to ah arbitrary position in the Auto Increment mode may have

RIGHT ENTRY MODE (AUTO INCREMENT)

arbitrary position in the Auto Increment mode may have unexpected results. Entry starting at Display RAM address

0 with sequential entry is recommended.

### Auto Increment not valuable transfer of the Increment and Increm

In the Left Entry mode, Auto Incrementing causes the address where the CPU will next write to be incremented by one and the character appears in the next location. With non-Auto Incrementing the entry is both to the same RAM address and display position. Entry to an arbitrary address in the Auto Increment mode has no undesirable side effects and the result is predictable:

	0	1	2	3	4	5	6	7
2nd entry	1	2	10	erij	loc	שר	110	1
assion an along wit	0	1	2	3	4	5	6	7
Command 10010101		2	3.	ani	T	TH	8 13	1
	En	ter	nex	t at	Lo	cati	on !	5 A
losed swit	-	dio	2	3	4	5	6	
3rd entry	1	2	.en	0.8	lett.	3	tac	6
	170773333							
	0	1	2	3		3		7

(AUTO INCREMENT)
In the Right Entry mode, Auto Incrementing and

In the Right Entry mode, Auto Incrementing and non Incrementing have the same effect as in the Left Entry except if the address sequence is interrupted:

1	2	3	4	5	6	7	0-	← Display
	a la la	i,	134	do	8.0	101	1	RAM Address
	TYY	b.	1		1.	1	_	
	3	4						
2010	qal					1	_	
	2	2 3	2 3 4	2 3 4 5	2 3 4 5 6	2 3 4 5 6 7	2 3 4 5 6 7 0	2 3 4 5 6 7 0 1 2 3 4 5 6 7 0 1 1 2 2 3 4 5 6 7 0 1

	3	4	5	6	7	0	1	2
3rd entry	retr	el b	3	90	170	1	2	ei ei
		ows	9	opi	iod	de	9	T
	4	5	6	1	0	1	2	3

RIGHT ENTRY MODE (AUTO INCREMENT)

Starting at an arbitrary location operates as shown below:

	0	1	2	3	4	5	6	7-	Display
Command 10010101		30	ing fi	10			PHE		RAM Address
	En	tor	nov	+	10	anti	00 6	Auto	Ingramas

4 5 6 7 3 0 1st entry 2 3 4 5 6 7 0 2nd entry 8th entry 8 2 3 9th entry 6 8 9 2 3 4

Entry appears to be from the initial entry point.

# 8/16 Character Display Formats seems a si sidt . solveb

If the display mode is set to an 8 character display, the on duty-cycle is double what it would be for a 16 character display (e.g., 5.1 ms scan time for 8 characters vs. 10.3 ms for 16 characters with 100 kHz internal frequency).

Maximum Ratings" may cause permanent damage to

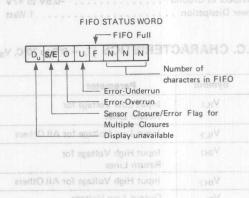

### G. FIFO Status

FIFO status is used in the Keyboard and Strobed Input modes to indicate the number of characters in the FIFO and to indicate whether an error has occurred. There are two types of errors possible: overrun and underrun. Overrun occurs when the entry of another character into a full FIFO is attempted. Underrun occurs when the CPU tries to read an empty FIFO.

The FIFO status word also has a bit to indicate that the Display RAM was unavailable because a Clear Display or Clear All command had not completed its clearing operation.

In a Sensor Matrix mode, a bit is set in the FIFO status word to indicate that at least one sensor closure indication is contained in the Sensor RAM.

In Special Error Mode the S/E bit is showing the error flag and serves as an indication to whether a simultaneous multiple closure error has occurred.

### INTRODUCTION TO THE UPI-41ATM

### Introduction

Since the introduction in 1974 of the second generation of microprocessors, such as the 8080, a wide range of peripheral interface devices have appeared. At first, these devices solved application problems of a general nature; i.e., parallel interface (8255), serial interface (8251), timing (8253), interrupt control (8259). However, as the speed and density of LSI technology increased, more and more intelligence was incorporated into the peripheral devices. This allowed more specific application problems to be solved, such as floppy disk control (8271), CRT control (8275), and data link control (8273). The advantage to the system designer of this increased peripheral device intelligence is that many of the peripheral control tasks are now handled externally to the main processor in the peripheral hardware rather than internally in the main processor software. This reduced main processor overhead results in increased system throughput and reduced software complexity.

In spite of the number of peripheral devices available, the pervasiveness of the microprocessor has been such that there is still a large number of peripheral control applications not yet satisfied by dedicated LSI. Complicating this problem is the fact that new applications are emerging faster than the manufacturers can react in developing new, dedicated peripheral controllers. To address this problem, a new microcomputer-based Universal Peripheral Interface (UPI-41A) device was developed.

In essence, the UPI-41A acts as a slave processor to the main system CPU. The UPI contains its own processor, memory, and I/O, and is completely user programmable; that is, the entire peripheral control algorithm can be programmed locally in the UPI, instead of taxing the master processor's main memory. This distributed processing concept allows the UPI to handle the real-time tasks such as encoding keyboards, controlling printers, or multiplexing displays, while the main processor is handling non-realtime dependent tasks such as buffer management or arithmetic. The UPI relies on the master only for initialization, elementary commands, and data transfers. This technique results in an overall increase in system efficiency since both processorsthe master CPU and the slave UPI-are working in parallel.

This application note presents three UPI-41A applications which are roughly divided into two groups: applications whose complexity and UPI code space

requirements allow them to either stand alone or be incorporated as just one task in a "multi-tasking" UPI, and applications which are complete UPI applications in themselves. Applications in the first group are a simple LED display and sensor matrix controllers. A combination serial/parallel/ I/O device is an application in the second group. Each application illustrates different UPI configurations and features. However, before the application details are presented, a section on the UPI/master protocol requirements is included. These protocol requirements are key to UPI software development. For convenience, the UPI block diagram is reproduced in Figure 1 and the instruction set summary in Table 1.

### UPI-41 vs. UPI-41A

The UPI-41A is an enhanced version of the UPI-41. It incorporates several architectural features not found on the "non-A" device:

- Separate Data In and Data Out data bus buffer registers
- User-definable STATUS register bits
- Programmable master interrupts for the OBF and IBF flags
- Programmable DMA interface to external DMA controller.

   Quality years a mergor 9. Ar emply

The separate Data In (DBBIN) and Data Out (DBBOUT) registers greatly simplify the master/UPI protocol compated to the UPI-41. The master need only check IBF before writing to DBBIN and OBF before reading DBBOUT. No data bus buffer lock-out is required.

The most significant nibble of the STATUS register, undefined in the UPI-41, is user-definable in UPI-41A. It may be loaded directly from the most significant nibble of the Accumulator (MOV STS,A). These extra four STATUS bits are useful for transferring additional status information to the master. This application note uses this feature extensively.

A new instruction, EN FLAGS, allows OBF and  $\overline{\rm IBF}$  to be reflected on PORT 2 BIT 4 and PORT 2 BIT 5 respectively. This feature enables interrupt-driven data transfers when these pins are interrupt sources to the master.

By executing an EN DMA instruction PORT 2 BIT 6 becomes a DRQ (DMA Request) output and PORT 2 BIT 7 becomes DACK (DMA Acknowledge). Setting DRQ requests a DMA cycle to an external DMA controller. When the cycle is granted, the DMA controller returns DACK plus either RD (Read) or WR (Write). DACK automatically forces

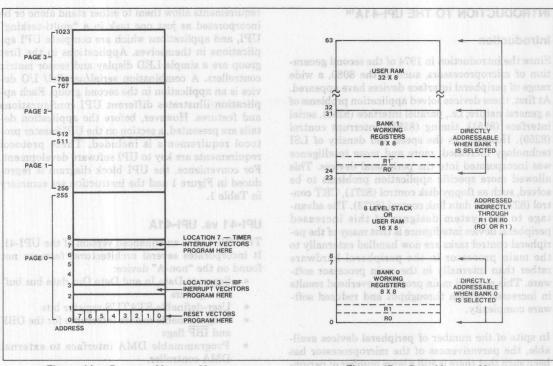

Figure 1A. Program Memory Map

Figure 1B. Data Memory Map

 $\overline{\text{CS}}$  and  $A_0$  low internally and clears DRQ. This selects the appropriate data buffer register (DBBOUT for DACK and  $\overline{\text{RD}}$ , DBBIN for DACK and  $\overline{\text{WR}}$ ) for the DMA transfer.

Like the "non-A", the UPI-41A is available in both ROM (8041A) and EPROM (8741A) Program Memory versions. This application note deals exclusively with the UPI-41A since the applications use the "A"s enhanced features.

### **UPI/MASTER PROTOCOL**

As in most closely coupled multiprocessor systems, the various processors communicate via a shared resource. This shared resource is typically specific locations in RAM or in registers through which status and data are passed. In the case of a master processor and a UPI-41A, the shared resource is 3 separate, master-addressable, registers internal to the UPI. These registers are the status register (STATUS), the Data Bus Buffer Input register (DBBIN), and the Data Bus Output register (DBBOUT). [Data Bus Buffer direction is relative to the UPI]. To illustrate this register interface, consider the 8085A/UPI system in Figure 2.

Looking into the UPI from the 8085A, the 8085A sees only the three registers mentioned above. If the 8085A wishes to issue a command to the UPI, it does so by writing the command to the DBBIN register according to the decoding of Table 2. Data for the UPI is also passed via the DBBIN register. (The UPI differentiates commands and data by examining the A<sub>0</sub> pin. Just how this is done is covered shortly.) Data from the UPI for the 8085A is passed in the DBBOUT register. The 8085A may interrogate the UPI's status by reading the UPI's STATUS register. Four bits of the STATUS register act as flags and are used to handshake data and commands into and out of the UPI. The STATUS register format is shown in Figure 3.

BIT 0 is OBF (Output Buffer Full). This flag indicates to the master when the UPI has placed data in the DBBOUT register. OBF is set when the UPI writes to DBBOUT and is reset when the master reads DBBOUT. The master finds meaningful data in the DBBOUT register only when OBF is set.

The Input Buffer Full (IBF) flag is BIT 1. The UPI uses this flag as an indicator that the master has written to the DBBIN register. The master uses IBF

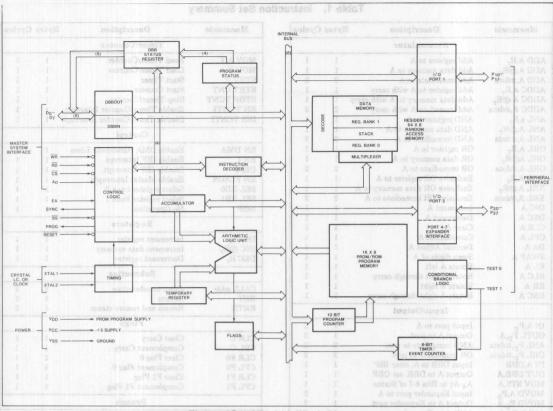

Figure 1C. UPI-41A Block Diagram

to indicate when the UPI has accepted a particular command or data byte. The master should examine IBF before outputting anything to the UPI. IBF is set when the master writes to DBBIN and is reset when the UPI reads DBBIN. The master must wait until IBF=0 before writing new data or commands to DBBIN. Conversely, the UPI must ensure IBF=1 before reading DBBIN.

The third STATUS register bit is  $F_0$  (FLAG 0). This is a general purpose flag that the UPI can set, reset, and test. It is typically used to indicate a UPI error or busy condition to the master.

FLAG 1  $(F_1)$  is the final dedicated STATUS bit. Like  $F_0$  the UPI can set, reset, and test this flag. However, in addition,  $F_1$  reflects the state of the  $A_0$  pin whenever the master writes to the DBBIN register. The UPI uses this flag to delineate between master command and data writes to DBBIN.

The remaining four STATUS register bits are user definable. Typical uses of these bits are as status in-

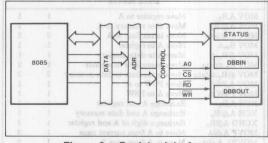

Figure 2. Register Interface

dicators for individual tasks in a multitasking UPI or as UPI generated interrupt status. These bits find a wide variety of uses in the upcoming applications.

Looking into the 8085A from the UPI, the UPI sees the two DBB registers plus the IBF, OBF, and F<sub>1</sub> flags. The UPI can write from its accumulator to DBBOUT or read DBBIN into the accumulator. The UPI cannot read OBF, IBF, or F<sub>1</sub> directly, but these flags may be tested using conditional jump

and test. It is typically used to indicate a UPI error

Figure 3. Status Register Format daniels

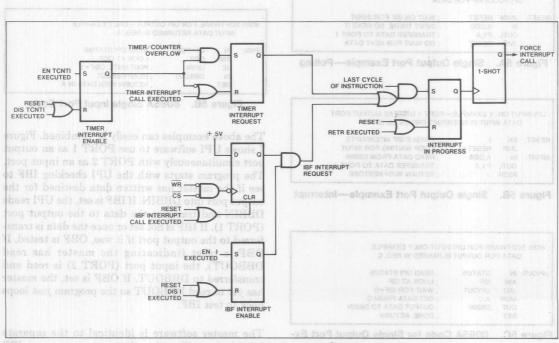

instructions. The UPI should make sure that OBF is reset before writing new data into DBBOUT to ensure that the master has read previous DBBOUT data. IBF should also be tested before reading DBBIN since DBBIN data is valid only when IBF is set. As was mentioned earlier, the UPI uses F1 to differentiate between command and data contents in DBBIN when IBF is set. The UPI may also write the upper 4-bits of its accumulator to the upper 4-bits of the STATUS register. These bits are thus user definable.

The UPI can test the flags at any time during its internal program execution. It essentially "polls" the STATUS register for changes. If faster response is needed to master commands and data, the UPI's internal interrupt structure can be used. If IBF interrupts are enabled, a master write to DBBIN (either command or data) sets IBF which generates an internal CALL to location 03H in program memory. At this point, working register contents can be saved using bank switching, the accumulator saved in a spare working register, and the DBBIN register read and serviced. The interrupt logic for the IBF interrupt is shown in Figure 4. A few observations concerning this logic are appropriate. Note that if the master writes to DBBIN while the UPI is still servicing the last IBF interrupt (a RETR instruction has not been executed), the IBF Interrupt Pending line

is made high which causes a new CALL to 03H as soon as the first RETR is executed. No ENI (Enable Interrupt) instruction is needed to rearm the interrupt logic as is needed in an 8080 or 8085A system; the RETR performs this function. Also note that executing a DIS I to disable further IBF interrupts does not clear a pending interrupt. Only a CALL to location 03H or RESET clears a pending IBF interrupt.

Keeping in mind that the actual master/UPI protocol is dependent on the application, probably the best way to illustrate correct protocol is by example. Let's consider using the UPI as a simple parallel I/O device. (This is a trivial application but it embodies all of the important protocol considerations.) Since the UPI may be either interrupt or non-interrupt driven internally, both cases are considered.

Let's take the easiest configuration first; using the UPI PORT 1 as an 8-bit output port. From the UPI's point-of-view, this is an input-only application since all that is required is that the UPI input data from the master. Once the master writes data to the UPI, the UPI reads the DBBIN register and transfers the data to PORT 1. No testing for commands versus data is needed since the UPI "knows" it only performs one task—no commands are needed.

151 January 19 January

Non-interrupt driven UPI software is shown in Figure 5A while Figure 5B shows interrupt based software. For Figure 5A, the UPI simply waits until it sees IBF go high indicating the master has written a data byte to DBBIN. The UPI then reads DBBIN, transfers it to PORT 1, and returns to waiting for the next data. For the interrupt-driven UPI, Figure 5B, once the EN I instruction is executed, the UPI simply waits for the IBF interrupt before handling the data. The UPI could handle other tasks during this waiting time. When the master writes the data to DBBIN, an IBF interrupt is generated which performs a CALL to location 03H. At this point the UPI reads DBBIN (no testing of IBF is needed since an IBF interrupt implies that IBF is set), transfers the data to PORT 1, and executes an RETR which returns program flow to the main program.

Software for the master 8085A is included in Figure 5C. The only requirement for the master to output data to the UPI is that it check the UPI to be sure the previous data had been taken before writing new data. To accomplish this the master simply reads the STATUS register looking for IBF=0 before writing the next data.

```

Figure 5C. 8085A Code for Single Output Port Example

Figure 6A illustrates the case where UPI PORT 2 is used as an 8-bit input port. This configuration is termed UPI output-only as the master does not write (input) to the UPI but simply reads either the STATUS or the DBBOUT registers. In this example only the OBF flag is used. OBF signals the master that the UPI has placed new port data in DBBOUT. The UPI loops testing OBF. When OBF is clear, the master has read the previous data and UPI then reads its input port (PORT 2) and places this data in DBBOUT. It then waits on OBF until the master reads DBBOUT before reading the input port again. When the master wishes to read the input port data. Figure 6B, it simply checks for OBF being set in the STATUS register before reading DBBOUT. While this technique illustrates proper protocol, it should be noted that it is not meant to be a good method of using the UPI as an input port since the master would never get the newest status of the port.

```
: UPI OUTPUT ONLY EXAMPLE—PORT 2 USED AS INPUT PORT
: PORT DATA IS AVAILABLE IN DBBOUT

RESET: JOBF RESET : LOOP IF OBF=1 (DATA NOT READ)
IN A,P2 : DBBOUT CLEAR, READ PORT

ANI OBF LOOK AT OBF
JZ UPIIN WAIT UNTIL OBF= 1
IN DBBOUT READ DBBOUT
RET RETURN WITH DATA IN A
```

Figure 6B. 8085A Single Input Port Code

The above examples can easily be combined. Figure 7 shows UPI software to use PORT 1 as an output port simultaneously with PORT 2 as an input port. The program starts with the UPI checking IBF to see if the master has written data destined for the output port into DBBIN. If IBF is set, the UPI reads DBBIN and transfers the data to the output port (PORT 1). If IBF is not set or once the data is transferred to the output port if it was, OBF is tested. If OBF is reset (indicating the master has read DBBOUT), the input port (PORT 2) is read and transferred to DBBOUT. If OBF is set, the master has yet to read DBBOUT so the program just loops back to test IBF.

The master software is identical to the separate input/output examples; the master must test IBF

```

             DBB. A
                          GO CHECK FOR INPUT
             RESET
```

Figure 7. Combination Output/Input Port Example

and OBF before writing output port data into DBBIN or before reading input port from DBBOUT respectively.

In all of the three examples above, the UPI treats information from the master solely as data. There has been no need to check if DBBIN information is a command rather than data since the applications do not require commands. But what if both PORTs 1 and 2 were used as output ports? The UPI needs to know into which port to put the data. Let's use a command to select which port.

Recall that both commands and data pass through DBBIN. The state of the  $A_0$  pin at the time of the write to DBBIN is used to distinguish commands from data. By convention, DBBIN writes with  $A_0$ =0 are for data, and those with  $A_0$ =1 are commands. When DBBIN is written into,  $F_1$  (FLAG 1) is set to the state of  $A_0$ . The UPI tests  $F_1$  to determine if the information in the DBBIN register is data or command.

For the case of two output ports, let's assume that the master selects the desired port with a command prior to writing the data. (We could just use  $F_1$  as a port select but that would not illustrate the subtle differences between commands and data). Let's define the port select commands such that BIT 1=1 if the next data is for PORT 1 (Write PORT 1=0000 0010) and BIT 2=1 if the next data is for PORT 2 (Write PORT 2=0000 0100). (The number of the set bit selects the port.) Any other bits are ignored. This assignment is completely arbitrary; we could use any command structure, but this one has the advantage of being simple.

Note that the UPI must "remember" from DBBIN write to write which port has been selected. Let's use  $F_0$  (FLAG 0) for this purpose. If a Write PORT 1 command is received,  $F_0$  is reset. If the command is Write PORT 2,  $F_0$  is set. When the UPI finds data in DBBIN,  $F_0$  is interrogated and the data is loaded into the previously selected port. The UPI software is shown in Figure 8A.

Figure 8A. Dual Output Port Example

Initially, the UPI simply waits until IBF is set indicating the master has written into DBBIN. Once IBF is set, DBBIN is read and  $F_1$  is tested for a command. If  $F_1$ =1, the DBBIN byte is a command. Assuming a command, BIT 1 is tested to see if the command selected PORT 1. If so,  $F_0$  is cleared and the program returns to wait for the data. If BIT 1=0, BIT 2 is tested. If BIT 2 is set, PORT 2 is selected so  $F_0$  is set. The program then loops back waiting for the next master input. This input is the desired port data. If BIT 2 was not set,  $F_0$  is not changed and no action is taken.

When IBF=1 is again detected, the input is again tested for command or data. Since it is necessarily data, DBBIN is read and F<sub>0</sub> is tested to determine which port was previously selected. The data is then output to that port, following which the program waits for the next input. Note that since F<sub>0</sub> still selects the previous port, the next input could be more data for that port. The port selection command could be thought of as a port select flip-flop control; once a selection is made, data may be repeatedly written to that port until the other port is selected. Master software, Figure 8B, simply must check IBF before writing either a command or data to DBBIN. Otherwise, the master software is straightforward.

For the sake of completeness, UPI software for implementing two input ports is given in Figure 9. This case is simpler than the dual output case since the UPI can assume that all writes to DBBIN are port selection commands so no command/data testing is required. Once the Port Read command is input, the selected port is read and the port data is placed in DBBOUT. Note that in this case F<sub>0</sub> is used as a UPI

error indicator. If the master happened to issue an invalid command (a command without either BIT 1 or 2 set), F<sub>0</sub> is set to notify the master that the UPI did not know how to interpret the command. F<sub>0</sub> is also set if the master commanded a port read before it had read DBBOUT from the previous command. The UPI simply tests OBF just prior to loading DBBOUT and if OBF=1, F<sub>0</sub> is set to indicate the error.

All of the above examples are, in themselves, rather trivial applications of the UPI although they could easily be incorporated as one of several tasks in a UPI handling multiple small tasks. We have covered them primarily to introduce the UPI concept and to illustrate some master/UPI protocol. Before moving on to more realistic UPI applications, let's discuss two UPI features that do not directly relate to the master/UPI protocol but greatly enhance the UPI's transfer capability.

In addition to the OBF and IBF bits in the STATUS register, these flags can also be made available directly on two port pins. These port pins can then be used as interrupt sources to the master. By executing an EN FLAGS instruction, PORT 2 pin 4 reflects the condition of OBF and PORT 2 pin 5 reflects the inverted condition of IBF (IBF). These dedicated outputs can then be enabled or disabled via their respective port bit values; i.e., P24 reflects OBF as long as an instruction is executed which sets P24 (i.e. ORL P2,#10H). The same action applies to the IBF output except P25 is used. Thus P24 may serve as a DATA AVAILABLE interrupt output. Likewise for P25 as a READY-TO-ACCEPT-DATA interrupt. This greatly simplifies interrupt-driven master-slave data transfers.

Figure 9. Dual Input Port Example

 $(\overline{DACK})$  input. Any instruction which would normally set P26 now sets DRQ. DRQ is cleared when  $\overline{DACK}$  is low and either  $\overline{RD}$  or  $\overline{WR}$  is low. When  $\overline{DACK}$  is low,  $\overline{CS}$  and A0 are forced low internally which allows data bus transfers between DBBOUT or DBBIN to occur, depending upon whether  $\overline{WR}$  or  $\overline{RD}$  is true. Of course, the function requires the use of an external DMA controller.

Now that we have discussed the aspects of the UPI protocol and data transfer interfaces, let's move on to the actual applications.

# EXAMPLE APPLICATIONS AND ALLER OF THE PROPERTY 
Each of the following three sections presents the hardware and software details of a UPI application. Each application utilizes one of the protocols mentioned in the last section. The first example is a simple 8-digit LED display controller. This application requires only that the UPI perform input operations from the DBBIN; DBBOUT is not used. The reverse is true for the second application: a sensor matrix controller. The final application involves both DBBOUT and DBBIN operations: a combination serial/parallel I/O device.

The core master processor system with which these applications were developed is the iSBC 80/30 single board computer. This board provides an especially convenient UPI environment since it contains a dedicated socket specifically interfaced for the UPI-41A. The 80/30 uses the 8085A as the master processor. The I/O and peripheral complement on the 80/30 include 12 vectored priority interrupts (8 on an 8259 Programmable Interrupt Controller and 4 on the 8085A itself), an 8253 Programmable Interval Timer supplying three 16-bit programmable timers (one is dedicated as a programmable baud rate generator), a high speed serial channel provided by a 8251 Programmable USART, and 24 parallel I/O

lines implemented with an 8255A Programmable Parallel Interface. The memory complement contains 16K bytes of RAM using 2117 16K bit Dynamic RAMs and the 8202 Dynamic RAM Controller, and up to 8K bytes of ROM/EPROM with sockets compatible with 2716, 2758, or 2332 devices. The 80/30's RAM uses a dual port architecture. That is, the memory can be considered a global system resource, accessible from the on-board 8085A as well as from remote CPUs and other devices via the MULTIBUS. The 80/30 contains MULTIBUS control logic which allows up to 16 80/30s or other bus masters to share the same system bus. (More detailed information on the iSBC 80/30 and other iSBC products may be found in the latest Intel Systems Data Catalog.)

A block diagram of the iSBC 80/30 is shown in Figure 10. Details of the UPI interface are shown in Figure 11. This interface decodes the UPI registers in the following format:

Register
Read STATUS
Write DBBIN (command)
Pood DPPOUT (data)

### 8-Digit Multiplexed LED Display

The traditional method of interfacing an LED display with a microprocessor is to use a data latch along with a BDC-to-7-segment decoder for each digit of the display. Thus two ICs, seven current limiting resistors, and about 45 connections are required for each digit. These requirements are, of course, multiplied by the total number of digits desired. The obvious disadvantages of this method are high parts count and high power dissipation since each digit is "ON" continuously. Instead, a scheme of time multiplexing the display can be used to decrease both parts count and power dissipation.

Display multiplexing basically involves connecting the same segment (a, b, c, d, e, f, or g) of each digit in parallel and driving the common digit element (anode or cathode) of each digit separately. This is shown schematically in Figure 12. The various digits of the display are not all on at once; rather, only one digit at a time is energized. As each digit is energized, the appropriate segments for that digit are turned on. Each digit is enabled in this way, in sequence, at a rate fast enough to ensure that each digit appears to be "ON" continuously. This implies that the display must be "refreshed" at periodic intervals to keep the digits flicker-free. If the CPU had to handle this task, it would have to suspend normal

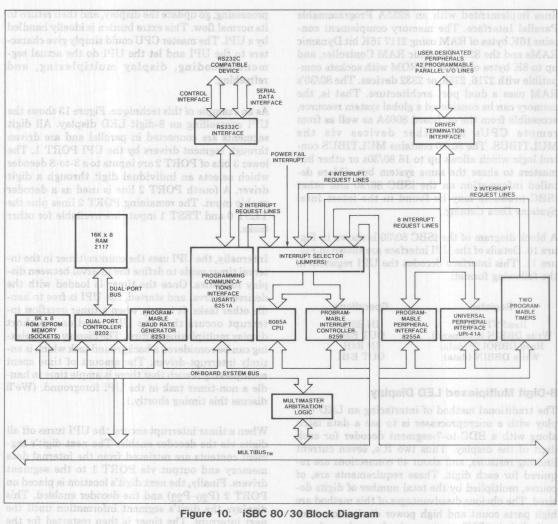

processing, go update the display, and then return to its normal flow. This extra burden is ideally handled by a UPI. The master CPU could simply give characters to the UPI and let the UPI do the actual segment decoding, display multiplexing, and refreshing.

As an example of this technique, Figure 13 shows the UPI controlling an 8-digit LED display. All digit segments are connected in parallel and are driven through segment drivers by the UPI PORT 1. The lower 3 bits of PORT 2 are inputs to a 3-to-8 decoder which selects an individual digit through a digit driver. A fourth PORT 2 line is used as a decoder enable input. The remaining PORT 2 lines plus the TEST 0 and TEST 1 inputs are available for other tasks.

Internally, the UPI uses the counter/timer in the interval timer mode to define the interval between display refreshes. Once the timer is loaded with the desired interval and started, the UPI is free to handle other tasks. It is only when a timer overflow interrupt occurs that the UPI handles the short display multiplexing routine. The display multiplexing can be considered a background task which is entirely interrupt-driven. The amount of time spent multiplexing is such that there is ample time to handle a non-timer task in the UPI foreground. (We'll discuss this timing shortly.)

When a timer interrupt occurs, the UPI turns off all digits via the decoder enable. The next digit's segment contents are retrieved from the internal data memory and output via PORT 1 to the segment drivers. Finally, the next digit's location is placed on PORT 2 (P20-P22) and the decoder enabled. This displays the digit's segment information until the next interrupt. The timer is then restarted for the next interval. This process continues repeatedly for each digit in sequence.

As a prelude to discussing the UPI software, let's examine the internal data memory structure used in this application, Figure 14. This application requires only 14 of the 64 total data memory locations. The top eight locations are dedicated to the Display Map; one location for each digit. These locations contain the segment and decimal point information for each character. Just how characters are loaded into this section of memory is covered shortly. Register R7 of Register Bank 1 is used as the temporary Accumulator store during the interrupt service routines. Register R3 stores the digit number of the next digit to be displayed. R2 is a temporary storage register for characters during input routine. R0 is

the offset pointer pointing to the Display Map location of the next digit. That makes 12 locations so far. The remaining two locations are the two stack locations required to store the return address plus status during the timer and input interrupt service routines. The remaining unused locations, all of Register Bank 0, 14 bytes of stack, 4 in Register Bank 1, and 24 general purpose RAM locations, are all available for use by any foreground task.

The UPI software consists of only three short routines. One, INIT, is used strictly during initialization. DISPLA is the multiplexing routine called at a timer interrupt. INPUT is the character input handler called at an IBF interrupt. The flow charts for these routines are shown in Figures 14A through 14C.

INIT initializes the UPI by simply turning off all segment and digit drivers, filling the Display Map with blank characters, loading and starting the timer, and enabling both timer and IBF interrupts. Although the flow chart shows the program looping at this point, it is here that the code for any foreground task is inserted. The only restrictions on this foreground task are that it not use I/O lines dedicated to the display and that it not require dedicated use of the timer. It could share the timer if precautions are taken to ensure that the display will still be refreshed at the required interval.

Figure 12. LED Multiplaxing

gg .....

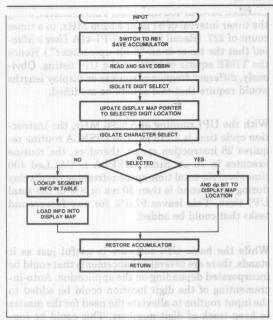

Figure 14B. INPUT Routine Flow

The INPUT routine handles the character input. It is called when an IBF interrupt occurs. After the usual swapping of register banks and saving of the accumulator, DBBIN is read and stored in register Ro. DBBIN contains the Display Data Word. The format for this word. Figure 15, has two fields: Digit Select and Character Select. The Digit Select field selects the digit number into which the character from the Character Select field is placed. Notice that the character set is not limited strictly to numerics. some alphanumeric capability is provided. Once DBBIN is read, the offset for the selected digit is computed and placed in the Display Map Pointer Ro. Next the segment information for the selected character is found through a look-up table starting in page 3 of the program memory. This segment information is then stored at the location pointed at by the Display Map Pointer. If the Character Select field specified a decimal point, the segment corresponding to the decimal point is ANDed into the present segment information for that digit. After the accumulator is restored, execution is returned to the main program, woods tada odd goddaglasgio xittem

The DISPLA routine simply implements the multiplexing actions described earlier. It is called whenever a timer interrupt occurs. After saving pre-

This arrangement of 16 sensors requires only 4 input

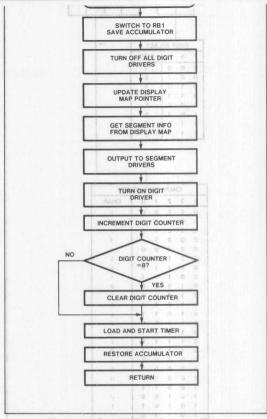

Figure 14C. DISPLA Routine Flow

interrupt status by switching register banks and storing the Accumulator, all digit drivers are turned off. The Display Map Pointer is then updated using the Current Digit Register to point at that digit's segment information in the Display Map. This information is output to PORT 1; the segment drivers. The number of the current digit, R3, is then sent to the digit select decoder and the decoder is enabled. This turns on the current digit. The digit counter is incremented and tested to see if all eight digits have been refreshed. If so, the digit counter is reset to zero. If not, nothing is done, Finally, the timer is loaded and restarted, the Accumulator is restored, and the routine returns execution to the main program. Thus DISPLA refreshes one digit each time it is CALLed by the timer interrupt. The digit remains on until the next time DISPLA is executed.

The UPI software listing is included as Appendix A1. Appendix A2 shows the 8085A test routine used

AFN-01536A

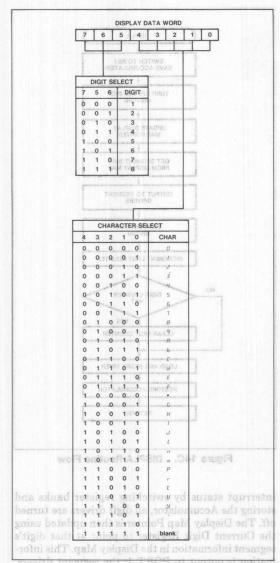

Figure 15. LED Display Controller Display Data Word Format

to display the contents of a display buffer on the display. The 8085A software takes care of the display digit numbering. Since the application is input-only for the UPI, the only protocol required is that the master must test IBF before writing a Display Data Word into DBBIN.

On the iSBC 80/30, the UPI frequency is at 5.5296 MHz. To obtain a flicker-free display, the whole display must be refreshed at a rate of 50 Hz or greater.

If we assume a 50 Hz refresh rate and an 8-digit display, this means the DISPLA routine must be CALLed  $50\times8$  or 400 times/sec. This transfers, using the timer interval of  $87~\mu s$  at 5.5296 MHz, to a timer count of 227. (Recall from the UPI-41A User's Manual that the timer is an "8-bit up-counter".) Hence the TIME equate of 227D in the UPI listing. Obviously, different frequency sources or display lengths would require that this equate be modified.

With the UPI running at 5.5296 MHz, the instruction cycle time is 2.713  $\mu$ s. The DISPLA routine requires 28 instruction cycles, therefore, the routine executes in 76  $\mu$ s. Since DISPLA is CALLed 400 times/sec, the total time spent refreshing the display during one second is then 30 ms or 3% of the total UPI time. This leaves 97.0% for any foreground tasks that could be added.

While the basic UPI software is useful just as it stands, there are several enhancements that could be incorporated depending on the application. Auto-incrementing of the digit location could be added to the input routine to alleviate the need for the master to keep track of digit numbers. This could be (optionally) either right-handed or left-handed entry a la TI or HP calculators. The character set could be easily modified by simply changing the lookup table. The display could be expanded to 16 digits at the expense of one additional PORT 2 digit select line, the replacement of the 3-to-8 decoder with a 4-to-16 decoder, and 8 more Display Map locations.

Now let's move on to a slightly more complex application that is UPI output-only—a sensor matrix controller.

# Sensor Matrix Controller

Quite often a microprocessor system is called upon to read the status of a large number of simple SPST switches or sensors. This is especially true in a process or industrial control environment. Alarm systems are also good examples of systems with a large sensor population. If the number of sensors is small, it might be reasonable to dedicate a single input port pin for each sensor. However, as the number of sensors increase, this technique becomes very wasteful. A better arrangement is to configure the sensors in a matrix organization like that shown in Figure 16. This arrangement of 16 sensors requires only 4 input and 4 output lines; half the number needed if dedicated inputs were used. The line saving becomes even more substantial as the number of sensors increases. sa 19ffA. atuooo tquatatai remit a tavenedw

In Figure 16, the basic operation of the matrix involves scanning individual row select lines in sequence while reading the column return lines. The state of any particular sensor can then be determined by decoding the row and column information. The typical configuration pulls up the column return lines and the selected row is held low. Deselected rows are held high. Thus a return line remains high for an open sensor on the selected row and is pulled low for a closed sensor. Diode isolation is used to prevent a phantom closure which would occur when a sensor is closed on a selected row and there are two or more closures on a deselected row. Germanium diodes are used to provide greater noise margin at the return line input.

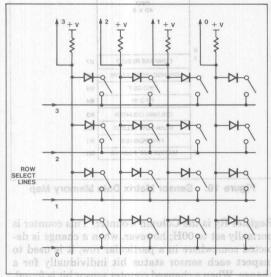

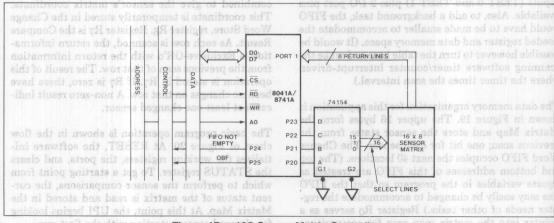

Figure 16. 4×4 Sensor Matrix

If the main processor was required to control such a matrix it would periodically have to output at the row port and then read the column return port. The processor would need to maintain in memory a map of the previous state of the matrix. A comparison of the new return information to the old information would then be made to determine whether a sensor change had occurred. Any changes would be processed as needed. A row counter and matrix map pointer also require maintenance each scan. Since in most applications sensors change very slowly compared to most processing actions, the processor probably would scan the rows only periodically with other tasks being processed between scans.

Rather than require the processor to handle the rather mundane tasks of scanning, comparing, and decoding the matrix, why not use a dedicated processor? The UPI is perfect.

Figure 17 shows a UPI configuration for controlling up to 128 sensors arranged in a 16×8 matrix. The 4to-16 line decoder is used as the row selector to save port pins and provides the expansion to 128 sensors over the maximum of 64 sensors if the port had been used directly. It also helps increase the port drive capability. The column return lines go directly into PORT 1. Features of this design include complete matrix management. As the UPI scans the matrix it compares its present status to the previous scan. If any change is detected, the location of the change is decoded and loaded, along with the sensor's present state, into DBBOUT. This byte is called a Change Word. The Master processor has only to read one byte to determine the status and coordinate of a changed sensor. If the master had not read a previous Change Word in DBBOUT (OBF=1) before a new sensor change is detected, the new Change

worden and this guide Figure 17. 128 Sensor Matrix Controller

Word is loaded into an internal FIFO. This FIFO buffers up to 40 changes before it fills. The status of the FIFO and OBF is made available to the master either by polling the UPI STATUS register, Figure 18A, or as interrupt sources on port pins P24 and P25 respectively, Figure 17. The FIFO NOT EMP-TY pin and bit are true as long as there are changes not yet read in the FIFO. As long as the FIFO is not empty, the UPI monitors OBF and loads new Change Words from the FIFO into DBBOUT. Thus, the UPI provides complete FIFO management.

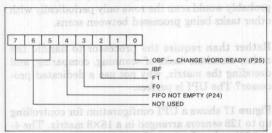

Figure 18A. Sensor Matrix Status Register Format

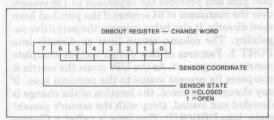

Figure 18B. Sensor Matrix Change Word Format

Internally, the matrix scanning software is programmed to run as a foreground task. This allows the timer/counter to be used by any background task although the hardware configuration leaves only 2 inputs (TEST 0 and TEST 1) plus 2 I/O port pins available. Also, to add a background task, the FIFO would have to be made smaller to accommodate the needed register and data memory space. (It would be possible however to turn the table here and make the scanning software timer/counter interrupt-driven where the timer times the scan interval.)

The data memory organization for this application is shown in Figure 19. The upper 16 bytes form the Matrix Map and store the sensor states from the previous scan; one bit for each sensor. The Change Word FIFO occupies the next 40 locations. (The top and bottom addresses of this FIFO are treated as equate variables in the program so that the FIFO size may easily be changed to accommodate the register needs of other tasks.) Register R0 serves as a pointer into the matrix map area for comparisons

and updates of the sensor status. R<sub>1</sub> is a general FIFO pointer. The FIFO is implemented as a circular buffer with In and Out pointer registers which are stored in R<sub>4</sub> and R<sub>5</sub> respectively. These registers are moved into FIFO pointer R<sub>1</sub> for actual transfers into or out of the FIFO. R<sub>2</sub> is the Row Select Counter. It stores the number of the row being scanned.

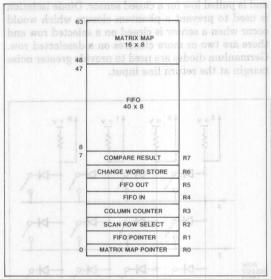

Figure 19. Sensor Matrix Data Memory Map

Register R3 is the Column Counter. This counter is normally set to 00H; however, when a change is detected somewhere in a particular row, it is used to inspect each sensor status bit individually for a change. When a changed counter sensor bit is found, the Row Select Counter and Column Counter are combined to give the sensor's matrix coordinate. This coordinate is temporarily stored in the Change Word Store, register R6. Register R7 is the Compare Result. As each row is scanned, the return information is Exclusive-OR'd with the return information from the previous scan of that row. The result of this operation is stored in R7. If R7 is zero, there have been no changes on that row. A non-zero result indicates at least one changed sensor.

The basic program operation is shown in the flow chart of Figure 20. At RESET, the software initializes the working registers, the ports, and clears the STATUS register. To get a starting point from which to perform the sensor comparisons, the current status of the matrix is read and stored in the Matrix Map. At this point, the UPI begins looking for changed sensors starting with the first row.

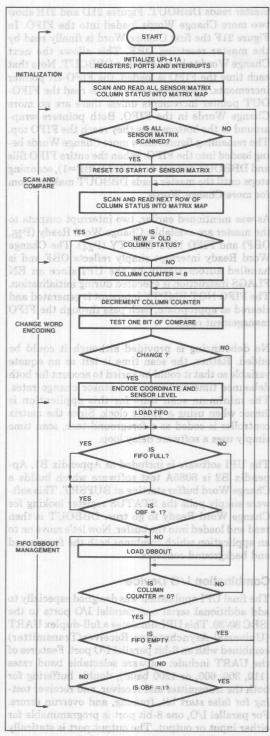

Figure 20. Sensor Matrix Controller Flow Chart

Before delving further into the flow, let's pause to describe the general format of the operation. The UPI scans the matrix one row at a time. If no changes are detected on a particular row, the UPI simply moves to the next row after checking the status of DBBOUT and the FIFO. If a change is detected, the UPI must check each bit (sensor) within the row to determine the actual sensor location. (More than one sensor on the scanned row could have changed.) Rather than test all 8 bits of the row before checking the DBBOUT and FIFO status again, the UPI performs the status check in between each of the bit tests. This ensures the fastest response to the master reading previous Change Words from DBBOUT and the FIFO.

With this general overview in mind, let's go first thru the flow chart assuming we are scanning a row where no changes have occurred. Starting at the Scan-and-Compare section, the UPI first checks if the entire matrix has been scanned. If it has, the various pointers are reset. If not, the address of the next row is placed on PORTs 20 thru 23. This selects the desired row. The state of the row is then read on PORT 1; the column return lines. This present state is compared to the previous state by retrieving the previous state from the matrix map and performing an Exclusive-OR with the present state. Since we are assuming that no change has occurred, the result is zero. No coordinate decoding is needed and the flow branches to the FIFO-DBBOUT Management section.

The FIFO-DBBOUT Management section simply maintains the FIFO and loads DBBOUT whenever Change Words are present in the FIFO and DBBOUT is clear (OBF=0). The section first tests if the FIFO is full. (If we assume our "no-change" row is the first row scanned, the FIFO obviously would not be full.) If it is, the UPI waits until OBF=0, at which point the next Change Word is retrieved from the FIFO and placed in DBBOUT. This "unfills" the FIFO making room for more Change Words. At this point, the Column Counter, R3, is checked. For rows with no changes, the Column Counter is always zero so the test simply falls through. (We cover the case for changes shortly.) Now the FIFO is tested for being empty. If it is, there is no sense in any further tests so the flow simply goes back up to scan the next row. If the FIFO is not empty, DBBOUT is tested again through OBF. If a Change Word is in DBBOUT waiting for the master to read it, nothing can be done and the flow likewise branches up for the next row. However, if the DBBOUT is free and remembering that the previous test showed that the FIFO was not empty, DBBOUT is loaded with the next Change Word and the last two conditional tests automotically acts OEF, OEF remains set unitagen

Now let's assume the next row contains several changed sensors. Like before, the row is selected, the return lines read, and the sensor status compared to the previous scan. Since changes have occurred, the Exclusive-OR result is now non-zero. Any 1's in the result reflect the positions of the changed sensors. This non-zero result is stored in the Compare Result register, R7. At this point, the Column Counter is preset to 8. To determine the changed sensors' locations, the Compare Result register is shifted bit-bybit to the left while decrementing the Column Counter. After each shift, BIT 7 of the result is tested. If it is a one, a changed sensor has been found. The Column Counter then reflected the sensor's matrix column position while the Scan Row Select register holds it row position. These registers are then combined in R6, the Change Word Store, to form the sensor's matrix coordinate section of the Change Word. The 8th bit of the Change Word Store is coded with the sensor's present state (Figure 18). This byte forms the complete Change Word. It is loaded into the next available FIFO position. If BIT 7 of the Compare Result had been zero, that particular sensor had not changed and the coordinate decoding is not performed.

In between each shift, test, and coordinate encode (if necessary), the FIFO-DBBOUT Management is performed. It is the Column Counter test within this section that routes the flow back up to the Change Word Encoding section if the entire Compare Result (row) has not been shifted and tested.

The FIFO is implemented as a circular buffer with IN and OUT pointers (R<sub>4</sub> and R<sub>5</sub> respectively). The operations of the FIFO is best understood using an example, Figure 21. This series of figures show how the FIFO, DBBOUT, and OBF interact as changes are detected and Change Words are read by the master. The letters correspond to sequential Change Words being loaded into the FIFO. Note that the figures show only a 4×8 FIFO however, the principles are the same in the 40×8 FIFO.

Figure 21A shows the condition where no Change Words have been loaded into the FIFO or DBBOUT. In Figure 21B a change, "A", has been detected, decoded, and loaded into the FIFO at the location equal to the value of the FIFO-IN pointer. The FIFO-OUT pointer is reset to the bottom of the FIFO since it had reached the FIFO top. Now that a Change Word is in the FIFO, OBF is checked to see if DBBOUT is empty. Because OBF=0, DBBOUT is empty and the Change Word is loaded from the FIFO location pointed at by the FIFO-OUT pointer. This is shown in Figure 21C. Loading DBBOUT automatically sets OBF. OBF remains set until the

master reads DBBOUT. Figures 21D and 21E show two more Change Words loaded into the FIFO. In Figure 21F the first Change Word is finally read by the master resetting OBF. This allows the next Change Word to be loaded into DBBOUT. Note that each time the FIFO is loaded, the FIFO-IN pointer increments. Each time DBBOUT is read the FIFO-OUT pointer increments unless there are no more Change Words in the FIFO. Both pointers wraparound to the bottom once they reach the FIFO top. The remaining figures show more Change Words being loaded into the FIFO. When the entire FIFO fills and DBBOUT can not be loaded (OBF=1), scanning stops until the master reads DBBOUT making room for more Change Words.

As was mentioned earlier, two interrupt outputs to the master are available: Change Word Ready (P<sub>25</sub>, OBF) and FIFO NOT EMPTY (P<sub>24</sub>). The Change Word Ready interrupt simply reflects OBF and is handled automatically by the UPI since an EN FLAGS instruction is executed during initialization. The FIFO NOT EMPTY interrupt is generated and cleared as appropriate, each pass through the FIFO management code.

No debouncing is provided although it could be added. Rather, the scan time is left as an equate variable so that it could be varied to account for both debounce time and expected sensor change rates. The minimum scan time for this application is 2msec when using a 6MHz clock. Since the matrix controller is coded as a foreground task, scan time simply uses a software delay loop.

The UPI software is included as Appendix B1. Appendix B2 is 8085A test software which builds a Change Word buffer starting at BUFSRT. This software simply polls the STATUS register looking for Change Word Ready to go true. DBBOUT is then read and loaded into the buffer. Now let's move on to an application which combines both the foreground and background concepts.

#### Combination I/O Device

The final UPI application was designed especially to add additional serial and parallel I/O ports to the iSBC 80/30. This UPI simulates a full-duplex UART (Universal Asynchronous Receiver/Transmitter) combined with an 8-bit parallel I/O port. Features of the UART include: software selectable baud rates (110, 300, 600, or 1200 baud), double buffering for both the transmitter and receiver, and receiver testing for false start bit, framing, and overrun errors. For parallel I/O, one 8-bit port is programmable for either input or output. The output port is statically latched and the input port is sampled.

AFN-01536A

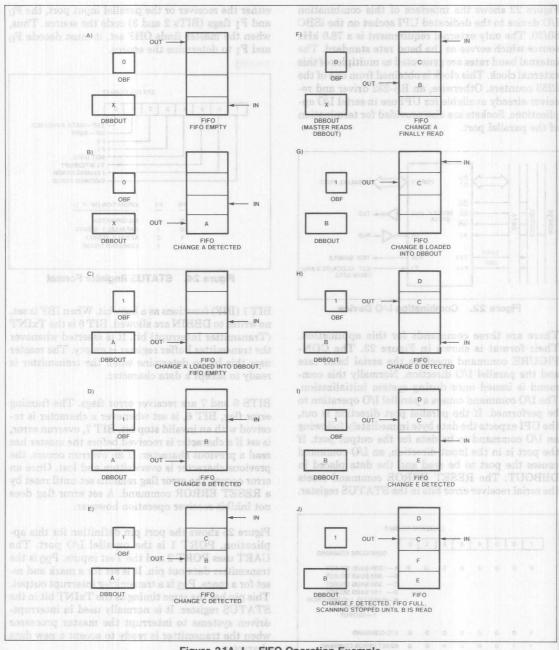

Figure 21A-J. FIFO Operation Example

Figure 22 shows the interface of this combination I/O device to the dedicated UPI socket on the iSBC 80/30. The only external requirement is a 76.8 kHz source which serves as the baud rate standard. The internal baud rates are generated as multiples of this external clock. This clock is obtained from one of the 8253 counters. Otherwise, an RS-232 driver and receiver already available for UPI use in serial I/O applications. Sockets are also provided for termination of the parallel port.

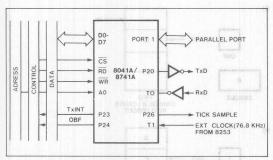

Figure 22. Combination I/O Device

There are three commands for this application. Their format is shown in Figure 23. The CON-FIGURE command specifies the serial baud rate and the parallel I/O direction. Normally this command is issued once during system initialization. The I/O command causes a parallel I/O operation to be performed. If the parallel port direction is out, the UPI expects the data byte immediately following an I/O command to be data for the output port. If the port is in the input direction, an I/O command causes the port to be read and the data placed in DBBOUT. The RESET ERROR command resets the serial receiver error bits in the STATUS register.

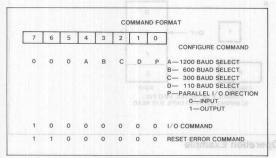

Figure 23. Combination I/O Command Format

The STATUS register format is shown in Figure 24. Looking at each bit, BIT 0 (OBF) is the DATA AVAILABLE flag. It is set whenever the UPI places data into DBBOUT. Since the data may come from

either the receiver or the parallel input port, the  $F_0$  and  $F_1$  flags (BITs 2 and 3) code the source. Thus, when the master finds OBF set, it must decode  $F_0$  and  $F_1$  to determine the source.

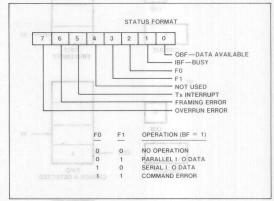

Figure 24. STATUS Register Format

BIT 1 (IBF) functions as a busy bit. When IBF is set, no writes to DBBIN are allowed. BIT 5 is the TxINT (Transmitter Interrupt) bit. It is asserted whenever the transmitter buffer register is empty. The master uses this bit to determine when the transmitter is ready to accept a data character.

BITS 6 and 7 are receiver error flags. The framing error flag, BIT 6, is set whenever a character is received with an invalid stop bit. BIT 7, overrun error, is set if a character is received before the master has read a previous character. If an overrun occurs, the previous character is overwritten and lost. Once an error occurs, the error flag remains set until reset by a RESET ERROR command. A set error flag does not inhibit receiver operation however.

Figure 25 shows the port pin definition for this application. PORT 1 is the parallel I/O port. The UART uses PORT 2 and the Test inputs.  $P_{20}$  is the transmitter data out pin. It is set for a mark and reset for a space.  $P_{23}$  is a transmitter interrupt output. This pin has the same timing as the TxINT bit in the STATUS register. It is normally used in interrupt-driven systems to interrupt the master processor when the transmitter is ready to accept a new data character.

The OBF flag is brought out on  $P_{24}$  as a master interrupt when data is available in DBBOUT.  $P_{26}$  is a diagnostic pin which pulses at four times the selected baud rate. (More about this pin later.) The receiver data input uses the TEST 0 input. One of the PORT 2 pins could have been used, however, the

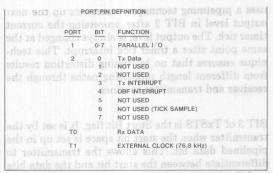

Figure 25. Combination I/O Port Definition

software can test the TEST 0 in one instruction without first reading a port.

The TEST 1 input is the baud rate external source. The UART divides this input to determine the timing needed for the selected baud rate. The input is a non-synchronous 76.8 kHz source.

Internally, when the CONFIGURE command is received and the selected baud rate is determined, the internal timer/counter is loaded with a baud rate constant and started in the event counter mode. Timer/counter interrupts are then enabled. The baud rate constant is selected to provide a counter interrupt at four times the desired baud rate. At each interrupt, both the transmitter and receiver are handled. Between interrupts, any new commands and data are recognized and executed.

As a prelude to discussing the flow charts, Figure 26 shows the register definition. Register Bank 0 serves the UART receiver and parallel I/O while Register Bank 1 handles the UART transmitter and commands. Looking at RB0 first, R3 is the receiver status register, RxSTS. Reflected in the bits of this register is the current receiver status in sequential order. Figure 27 shows this bit definition. BIT 0 is the Rx flag. It is set whenever a possible start bit is received. BIT 1 signifies that the start bit is good and character construction should begin with the next received bit. BIT 1 is the Good Start flag. BIT 2 is the Byte Finished flag. When all data bits of a character are received, this flag is set. When all the bits, data and stop bits are received, the assembled character is loaded into the holding register (R4 in Figure 27) BIT 3, the Data Ready flag, is set. The foreground routine which looks for commands and data continuously, looks at this bit to determine when the receiver has received a character. BITS 4 and 5 signify any error conditions for a particular character.

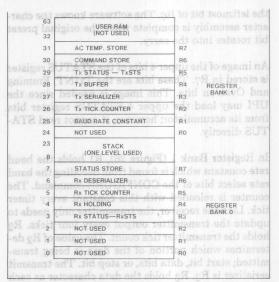

Figure 26. Combination I/O Register Map

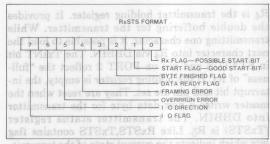

Figure 27. RxSTS Register

The parallel I/O port software uses BITS 6 and 7. BIT 6 codes the I/O direction specified by the last CONFIGURE command. BIT 7 is set whenever an I/O command is received. The foreground routine tests this bit to determine when an I/O operation has been requested by the master.

As was mentioned, R<sub>4</sub> is the receiver holding register. Assembled characters are held in this register until the foreground routine finds DBBOUT free, at which time the data is transferred from R<sub>4</sub> to DBBOUT. R<sub>5</sub> is the receiver tick counter. Recall that counter interrupts occur at four times the baud rate. Therefore, once a start bit is found, the receiver only needs to look at the data every four interrrupts or tick counts. R<sub>5</sub> holds the current tick count.

R<sub>6</sub> is the receiver de-serializing register. Data characters are assembled in this register. R<sub>6</sub> is preset to 80H when a good start bit is received. As each bit is

sampled every four timer ticks, they are rotated into the leftmost bit of R6. The software knows the character assembly is complete when the original preset bit rotates into the carry.

An image of the upper 4 bits of the STATUS register is stored in R7. These bits are the TxINT, Framing and Overrun bits. This image is needed since the UPI may load the upper 4 STATUS register bits from its accumulator; however, it cannot read STATUS directly.

In Register Bank 1 (Figure 26), R1 holds the baud rate constant which is found from decoding the baud rate select bits of the CONFIGURE command. The counter is reloaded with this constant every timer tick. Like the receiver, the transmitter only needs to update the transmitter output every four ticks. R2 holds the transmitter tick count. The value of R2 determines which portion of the data is being transmitted; start bit, data bits, or stop bit. The transmit serializer is R3. R3 holds the data character as each character bit is transmitted.

R<sub>4</sub> is the transmitter holding register. It provides the double buffering for the transmitter. While transmitting one character, it is possible to load the next character into R<sub>4</sub> via DBBIN. The TxINT bit in STATUS and pin on PORT 2 reflect the "fullness" of R<sub>4</sub>. If the holding register is empty, the interrupt bit and pin are set. They are reset when the master writes a new data byte for the transmitter into DBBIN. The transmitter status register (TxSTS) is R<sub>5</sub>. Like RxSTS,TxSTS contains flag bits which indicate the current state of the transmitter. This flag bit format is shown in Figure 28.

TxSTS BIT 0 is the Tx flag. It is set whenever the transmitter is transmitting a character. It is set from the beginning of the start bit until the end of the stop bit. BIT 1 is the Tx request flag. This bit is set by the foreground routine when it transfers a new character from DBBIN to the Tx holding register, R4. The transmitter software uses this flag to tell if new data is available. It is reset when the transmitter transfers the character from the holding register to the serializer.

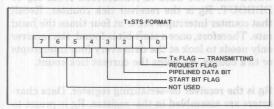

Figure 28. TxSTS Register

BIT 2 is the pipelined Tx data bit. The transmitter uses a pipelining technique which sets up the next output level in BIT 2 after processing the current timer tick. The output level is always changed at the same point after a timer tick interrupt. This technique ensures that no bit timing distortion results from different length processing paths through the receiver and transmitter routines.

BIT 3 of TxSTS is the Start Bit flag. It is set by the transmitter when the start bit space is set up in the pipelined data bit. This allows the transmitter to differentiate between the start bit and the data bits on following timer ticks.

The flow charts for this application are shown in Figures 29A-F. At reset, the INIT routine is executed which initializes the registers and port pins. After initialization, IBF and OBF are tested in MNLOOP. These flags are tested continually in this loop. If IBF is set, F1 is tested for command or data and execution is transferred to the appropriate routine (CMD or DATA). If IBF=0, OBF is checked. If OBF=0 (DBBOUT is free), the Rx data ready and I/O flags in RxSTS are tested. If Rx data ready is set. the received data is retrieved from the Rx holding register and transferred to DBBOUT. Any error flags associated with that data are also transferred to STATUS. If the I/O flag is set and the I/O direction is input, PORT 1 is read and the data transferred to DBBOUT. In either case, Fo and F1 are set to indicate the data source. stormstol resewied helbrad

If IBF is set by a command write to DBBIN, CMD reads the command and decodes the desired operation. If an I/O operation is specified, the I/O flag is set to indicate to the MNLOOP and DATA routines that an I/O operation is to be performed. If the command is a CONFIGURE command, the constant for the selected baud rate is loaded into both Baud Rate Constant register and the timer/counter. The timer/counter is started in the event counter mode and timer/counter interrupts are enabled. In addition, the I/O port is initialized to all 1's if the I/O direction bit specifies an input port. If the command is a RE-SET ERROR command, the two error flags in STA-TUS are cleared.

If the IBF flag is set by a data write, the DATA routine reads DBBIN and places the data in the appropriate place. If the I/O flag is set, the data is for the output port so the port is loaded. If the I/O flag is reset, the data is for the UART transmitter. Data for the transmitter resets the TxINT bit and pin plus sets the Tx request flag in TxSTS. The data is transferred to the Tx holding register, R4.

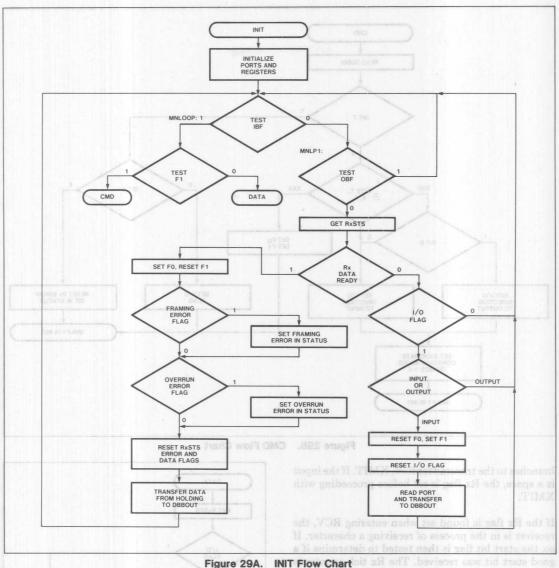

Figure 29A.

Once a CONFIGURE command is received and the counter started, timer/counter interrupts start occurring at four times the selected baud rate. These interrupts cause a vector to the TIMINT routine, Figure 29D. A 76.8 kHz counter input provides a 13.02 µs counter resolution. Since it requires several UPI instruction cycles to reload the counter, the counter is set to two counts less than the desired baud rate and the counter is reloaded in TIMINT synchronous with the second low-going transition after the interrupt. Once the counter is reloaded, an output port (P26) is toggled to give an external indication of internal counter interval. This is a helpful diagnostic feature. After the tick sample output, the pipelined transmitter data in TxSTS is output to the TxD pin. Although this occurs every timer tick, the pipelined data is changed only every fourth tick.

The receiver is now handled, Figure 29E. The Rx flag in RxSTS is examined to see if the receiver is currently in the process of receiving a character. If it is not, the RxD input is tested for a space condition which might indicate a possible start bit. If the input is a mark, no start bit is possible and execution

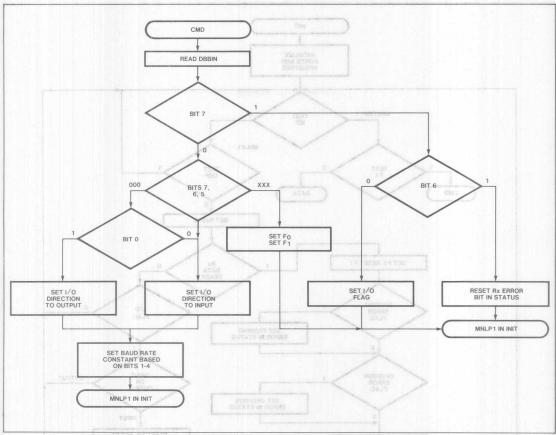

Figure 29B. CMD Flow Chart

branches to the transmitter flow, XMIT. If the input is a space, the Rx flag is set before proceeding with XMIT.

If the Rx flag is found set when entering RCV, the receiver is in the process of receiving a character. If so, the start bit flag is then tested to determine if a good start bit was received. The Rx tick counter is initialized to 4 and the Rx deserializer is set to 80H. A mark indicates a bad start bit; the Rx flag is reset to abort the reception.

If the start bit flag is set, the program is somewhere in the middle of the received character. Since the data should be sampled every fourth timer tick, the tick counter is decremented and tested for zero. If non-zero no sample is needed and execution continues with XMIT. If zero, the tick counter is reset to four. Now the byte finished flag is tested to determine if the data sample is a data or stop bit. If reset, the sample is a data bit. The sample is done and the new bit rotated into the Rx deserializer. If this rotate

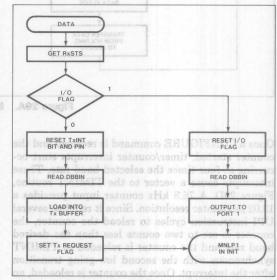

Figure 29C. Data Flow Chart

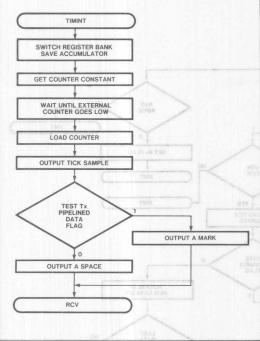

Figure 29D. TIMINT Flow Chart

sets the carry, that data bit was the last so the byte finished flag is set. If the carry is reset, the data bit is not the last so execution simply continues with XMIT.

Had the byte finished flag been set, this sample is for the stop bit. The RxD input is tested and if a space, the framing error flag is set. Otherwise, it is reset. Next, the Rx data ready flag is tested. If it is set, the master has not read the previous character so the overrun error flag is set. Then the Rx data ready flag is set and the received data character is transferred into the Rx holding register. The Rx, start bit, and byte finished flags are reset to get ready for the next character.

Execution of the transmitter routine, XMIT, follows the receiver, Figure 29F. The transmitter starts by checking the start bit flag in TxSTS. Recall that the actual transmit data is output at the beginning of the timer routine. The start bit flag indicates whether the current timer tick interrupt started the start bit. If it is set, the pipelined data output earlier in the routine was the start of the start bit so the flag is reset and the Tx tick counter is initialized. Nothing else is done this timer tick so the routine returns to the foreground.

In the start bit flag is reset, the Tx tick counter is incremented and tested. The test is performed modulo 4. If the counter mod 4 is not zero, it has not been four ticks since the transmitter was handled last so the routine simply returns. If the counter mod 4 is zero, it is time to handle the transmitter and the Tx flag is tested.

The Tx flag indicates whether the transmitter is active. If the transmitter is inactive, no character is currently being transmitted so the Tx request flag is tested to see if a new character is waiting in the Tx buffer. If no character is waiting (Tx request flag=0), the Tx interrupt pin and bit are set before returning to the foreground. If there is a character waiting, it is retrieved from the buffer and placed in the Tx serializer. The Tx request flag is reset while the Tx and start bit flags are set. A space is placed in the Tx pipelined data bit so a start bit will be output on the next tick. Since the Tx buffer is now empty, the Tx interrupt bit and pin are set to indicate the availability of the buffer to the master. The routine then returns to the foreground.

If the tick counter mod 4 is zero and the Tx flag indicates the transmitter is in the middle of a character, the tick counter is checked to see what transmitter operation is needed. If the counter is 28H (40D), all data bits plus the stop bits are complete. The character is therefore done and the Tx flag is reset. If the counter is 24H (36D), the data bits are complete and the next output should be a mark for the stop bit so a mark is loaded into the Tx pipelined data bit.

If neither of the above conditions are met for the counter, the transmitter is some place in the data field, so the next data bit is rotated out of the Tx serializer into the pipelined data bit. The next tick outputs this bit.

At this point the program execution is returned to the foreground.

That completes the discussion of the combination I/O device flow charts. The UPI software listing is shown in Appendix C1. Appendix C2 is example 8085A driver software.

Several observations concerning the drivers are appropriate. Notice that since the receiver and input port of the UPI use the OBF flag and interrupt output, the interrupt and flag are cleared when the master reads DBBOUT. This is not true for the transmitter. There is always some time after a master write of new transmitter data before the transmitter bit and pin are cleared. Thus in an interrupt-driven system, edge-sensitive interrupts should be

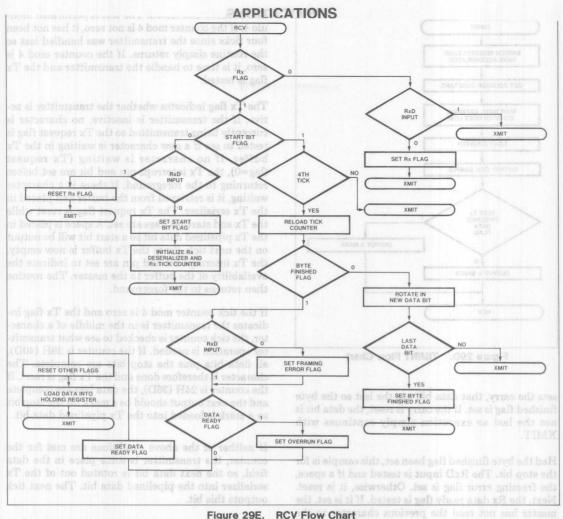

Figure 29E. RCV Flow Chart

used. For polled-systems, the software must wait after writing new data for IBF=0 before re-examining the Tx interrupt flag in STATUS.

Notice that this application uses none of the user data memory above Register Bank 1 and only 361 bytes of program memory. This leaves the door open for many improvements. Improvements that come to mind are increased buffering of the transmit or received data, modem control pins, and parallel port handshaking inputs.

This completes our discussion of specific UPI applications. Before concluding, let's look briefly at two debug techniques used during the development of

these applications that you might find useful in your own designs,

#### **DEBUG TECHNIQUES**

Since the UPI is essentially a single-chip microcomputer, the classical data, address, and control buses are not available to the outside world during normal operation. This fact normally makes debugging a UPI design difficult; however, certain "tricks" can be included in the UPI software to ease this task.

If a UPI is handling multiple tasks, it is usually easier to code and debug each task individually. This is fairly standard procedure. Since each task usually utilizes only a subset of the total number of I/O pins,

AFN-01536A

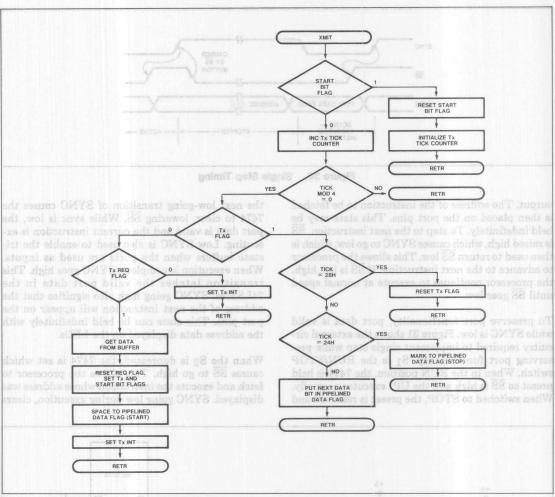

Figure 29F. XMIT Flow Chart

coding only one task leaves some I/O pins free. Port output instructions can then be added in the task code being debugged which toggle these unused pins to determine which section of task code is being executed at any particular time. The task can also be made to "wait" at various points by using an extra pin as an input and adding code to loop until a particular input condition is met.

One example of using an extra pin as an output is included in the combination serial/parallel device code. During initial development the receiver was not receiving characters correctly. Since this could be caused by incorrect sampling, three lines of code were added to toggle BIT 6 of PORT 2 at each tick of the sample clock. This code is at lines 184 and 185 of the listing. Thus by looking at the location of the tick

sample pulse with respect to the received bit, the UPI sampling interval can be observed. The tick sample time was incorrect and the code was modified accordingly. Similar techniques could be applied at other locations in the program.

The EPROM version of the UPI (8741A) also contains another feature to aid in debug: the capability to single step thru a program. The user may step thru the program instruction-by-instruction. The address of the next instruction to be fetched is available on PORT 1 and the lower 2 bits of PORT 2. Figure 30 shows the timing used in the discussion below. When the single step input,  $\overline{SS}$ , is brought low, the internal processor responds by stopping during the fetch portion of the next instruction. This action is acknowledged by the processor raising the SYNC

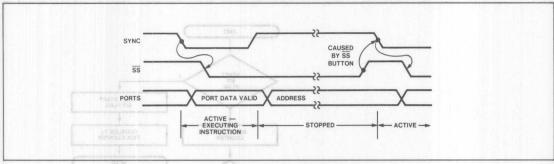

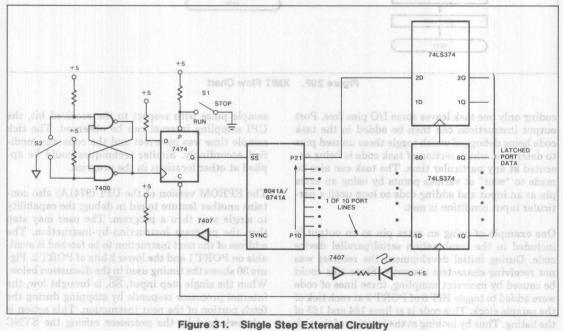

Figure 30. Single Step Timing

output. The address of the instruction to be fetched is then placed on the port pins. This state may be held indefinitely. To step to the next instruction, SS is raised high, which causes SYNC to go low, which is then used to return SS low. This allows the processor to advance to the next instruction. If SS is left high, the processor continues to execute at normal speed until SS goes low.

To preserve port functionality, port data is valid while SYNC is low. Figure 31 shows the external circuitry required to implement single step while preserving port functionality. S1 is the RUN/STOP switch. When in the RUN position, the 7474 is held preset so SS is high and the UPI executes normally. When switched to STOP, the preset is removed and

the next low-going transition of SYNC causes the 7474 to clear, lowering SS. While sync is low, the port data is valid and the current instruction is executing. Low SYNC is also used to enable the tristate buffers when the ports are used as inputs. When execution is complete, SYNC goes high. This transition latches the valid port data in the 74LS374s. SYNC going high also signifies that the address of the next instruction will appear on the port pins. This state can be held indefinitely with the address data displayed on the LEDs.

When the S2 is depressed, the 7474 is set which causes SS to go high. This allows the processor to fetch and execute the instruction whose address was displayed. SYNC going low during execution, clears

the 7474 lowering  $\overline{SS}$ . Thus the processor again stops when execution is complete and the next fetch is started.

All UPI functions continue to operate while single stepping (the processor is actually executing NOPs internally while stopped). Both IBF and timer/counter interrupts can be serviced. The only change is that the interval timer is prescaled on single stepped instructions and, of course, will not indicate the correct intervals in real time. The total number of instruction which would have been executed during a given interval is the same however.

The single step circuitry can be used to step through a complete program; however, this might be a time-consuming job if the program is long or if only a portion is to be examined. The circuitry could easily be modified to incorporate the output toggling technique to determine when to run and stop. If you would like to step thru a particular section of code,

an extra port pin could replace switch S<sub>1</sub>. Extra instructions would then be added to lower the port when entering the code section and raise the port when exiting the section. The program would then stop when that section of code is reached allowing it to be stepped through. At the end of the section, the program would execute at normal speed.

#### CONCLUSION

Well, that's it. Machine readable (floppy disk or paper tape) source listings of UPI software for these applications are available in Insite, the Intel library of user-donated programs. Also available in Insite are the source listings for some of Intel's pre-programmed UPI products.

For information about Insite, write to: Insite Intel Corp. 3065 Bowers Ave. Santa Clara, Ca 95051

the 7474 lowering SS. Thus the processor again stops when execution is complete and the next fetch is started.

All UPI functions continue to operate while single stepping (the processor is actually executing NOPs internally while stopped). Both IBF and timer/counter interrupts can be serviced. The only change is that the interval timer is prescaled on single stepped instructions and, of course, will not indicate the correct intervals in real time. The total number of instruction which would have been executed during a given interval is the same however.

The single step circuitry can be used to step through a complete program; however, this might be a time-consuming job if the program is long or if only a portion is to be examined. The circuitry could easily be modified to incorporate the output toggling technique to determine when to run and stop. If you would like to step thru a particular section of code,

an extra port pin could replace switch S<sub>1</sub>. Extra instructions would then he added to lower the port when entering the code section and raise the port when exiting the section. The program would then stop when that section of code is reached allowing it to be stepped through. At the end of the section, the program would execute at normal speed.

#### CONCLUSION

#### INTRODUCTION

The microcomputer system designer requiring a low-cost, non-volatile storage medium has a difficult choice. His options have been either relatively expensive, as with floppy discs and bubble memories, or non-transportable, like battery backed-up RAMs. The full-sized digital cassette option was open but many times it too was too expensive for the application. Filling this void of low-cost storage is the recently developed digital mini-cassette. These mini-cassettes are similar to, but not compatible with, dictation cassettes. The mini-cassette transports are inexpensive (well under \$100 in quantity), small (less than 25 cu. in.), low-power (one watt), and their storage capacity is a respectable 200K bytes of unformatted data on a 100-foot tape. These characteristics make the mini-cassette perfect for applications ranging from remote datalogging to program storage for hobbyist systems.

The only problem associated with mini-cassette drives is controlling them. While these drives are relatively easy to interface to a microcomputer system, via a parallel I/O port, they can quickly overburden a CPU if other concurrent or critical real-time I/O is required. The cleanest and probably

the least expensive solution in terms of development cost is to use a dedicated single-chip controller. However, a quick search through the literature turns up no controllers compatible with these new transports. What to do? Enter the UPI-41A family of Universal Peripheral Interfaces.

The UPI-41A family is a group of two user-programmable slave microcomputers plus a companion I/O expander. The 8741A is the "flag-chip" of the line. It is a complete microcomputer with 1024 bytes of EPROM program memory, 64 bytes of RAM data memory, 16 individually programmable I/O lines, an 8-bit event counter and timer, and a complete slave peripheral interface with two interrupts and Direct Memory Access (DMA) control. The 8041A is the masked ROM, pin compatible version of the 8741A. Figure 2 shows a block diagram common to both parts. The 8243 I/O port expander completes the family. Each 8243 provides 16 programmable I/O lines.

Using the UPI concept, the designer can develop a custom peripheral control processor for his particular I/O problem. The designer simply develops his peripheral control algorithm using the UPI-41A assembly language and programs the EPROM of

Figure 1. Comparison of Mini-Cassette and Floppy Disk Transports and Media.

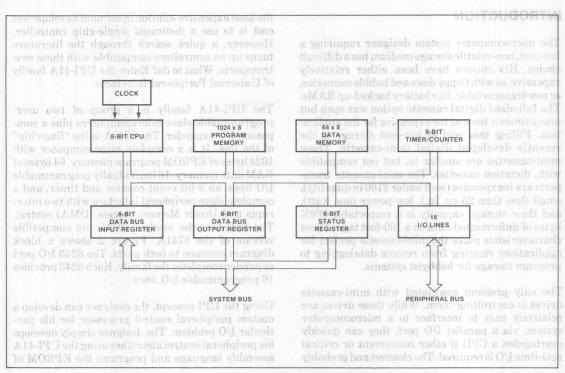

Figure 2. 8741A/8041A Block Diagram

the 8741A. Voila! He has a single-chip dedicated controller. Testing may be accomplished using either an ICE-41A or the Single-step mode of the 8741A. UPI-41A peripheral interfaces are being used to control printers, keyboards, displays, custom serial interfaces, and data encryption units. Of course, the UPI family is perfect for developing a dedicated controller for digital mini-cassette transports. To illustrate this application for the UPI family let's consider the job of controlling the Braemar CM-600 Mini-Dek®.

#### THE CM-600 MINI-DEK®

The Braemar CM-600 is representative of digital mini-cassette transports. It is a single-head, singlemotor transport which operates entirely from a single 5-volt power supply. Its power requirements, including the motor, are 200ma for read or write and 700ma for rewind. Tapes speeds are 3 inches per second (IPS) during read or write, 5 IPS fast forward, and 15 IPS rewind. With these speeds and a maximum recording density of 800 bits per inch (BPI), the maximum data rate is 2400 bits per second (BAUD). The data capacity using both sides the transport occupies only 22.5 cubic inches (3"x3"x2.5").

All I/O for the CM-600 is TTL-compatible and can be divided into three groups: motor control, data control, and cassette status. The motor group controls are GO/STOP, FAST/SLOW, and FORWARD/ REVERSE. The data controls are READ/WRITE, DATA IN, and DATA OUT. The remaining group of outputs give the transport's status: CLEAR LEADER, CASSETTE PRESENCE, FILE PRO-TECT, and SIDE SENSOR. These signals, shown schematically in figure 3 and table 1, give the pin definition of the CM-600 16-pin I/O connector.

#### RECORDING FORMAT

The CM-600 does not provide either encoding or decoding of the recorded data; that task is left for the peripheral interface. A multitude of encoding techniques from which the user may choose are available. In this single-chip dedicated controller application, a "self-clocking" phase encoding scheme similar to that used in floppy discs was chosen. This scheme specifies that a logic "0" is a bit cell with no of a 100-foot tape is 200K bytes. On top of this, transition; a cell with a transition is a logic "1."

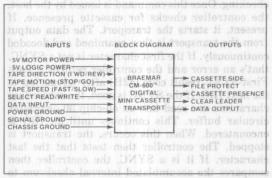

Figure 3. Braemar CM-600™ Block Diagram

Figure 4 illustrates the encoding of the character 3AH assuming the previous data ended with the data line high. (The least significant bit is sent first.) Notice that there is always a "clocking" transition at the beginning of each cell. Decoding is simply a matter of triggering on this "clocking" transition, waiting 3/4 of a bit cell time, and determining whether a mid-cell transition has occurred. Cells with no mid-cell transitions are data 0's; cells with transitions are data 1's. This encoding technique has all the benefits of Manchester encoding with the added advantage that the encoded data may be "decoded by eyeball:" long cells are always 0's, short cells are always 1's.

Besides the encoding scheme, the data format is also up to the user. This controller uses a variable byte length, checksum protected block format. Every block starts and ends with a SYNC character

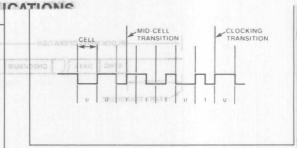

Figure 4. Modified Phase Encoding of Character 3A Hex

(AAH), and the character immediately preceeding the last SYNC is the checksum. The checksum is capable of catching 2 bit errors. The number of data characters within a block is limited to 64K bytes. Blocks are separated by an Inter-Record Gap (IRG). The IRG is of such a length that the transport can stop and start within an IRG, as illustrated in the data block timing, figure 5. Braemar specifies a maximum start or stop time of 150ms for the transport, thus the controller uses 450ms for the IRG. This gives plenty of margin for controlling the transport and also for detecting IRGs while skipping blocks.

#### THE UPI-41A CONTROLLER

The goal of the UPI software design for this application was to make the UPI-41A microcomputer into an intelligent cassette control processor. The host processor (8086, 8088, 8085A, etc.) simply issues a high-level command such as READ-a-block or WRITE-a-block. The 8741A accepts the command, performs the requested operation, and returns to the host system a result code telling the outcome of the operation, eg. Good-Completion, Sync Error, etc. Table 2 shows the command and result code repertoire. The 8741A completely manages all the data transfers for reading and writing.

As an example, consider the WRITE-a-block command. When this command is issued, the UPI-41A expects a 16-bit number from the host telling how many data bytes to write (up to 64K bytes per block). Once this number is supplied in the form of two bytes, the host is free to perform other tasks; a bit in the UPI's STATUS register or an interrupt output will notify the host when a data transfer is required. The 8741A then checks the transport's status to be sure that a cassette is present and not file protected. If either is false, a result code is

2-48 AFN-01342A

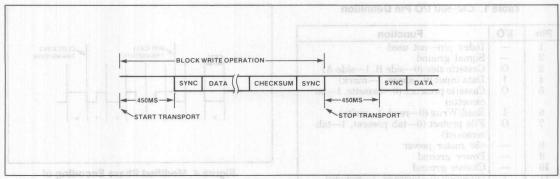

Figure 5. IRG/Block Timing Diagram (not to scale)

Table 2. Controller Command/Result Code Set

Command	Result no goni datas to alded
Read (01H)	Bad Synch1 Error (42H) Bad Synch2 Error (43H)
Rewind (04H)	Good-Completion (00H)
Skip (03H)	Good-Completion (00H) End of Tape Error (47H) Beginning of Tape Error (48H)
Write (02H)	Good-Completion (00H) Buffer Underrun Error (81H) Command Error (82H) End of Tape Error (83H)

returned to the host; otherwise the transport is started. After the peripheral controller checks to make sure that the tape is off the clear leader and past the hole in the tape, it writes a 450ms IRG, a SYNC character, the block of data, the checksum, and the final SYNC character. (The tape has a clear leader at both ends and a small hole 6 inches from the end of each leader.) The data transfers from the host to the UPI-41A slave microcomputer are double buffered. The controller requests only the desired number of data bytes by keeping track of the count internally.

If nothing unusual happened, such as finding clear leader while writing, it returns a Good-Completion result code to the host. If clear leader was encountered, the transport is stopped immediately and an End-of-Tape result code is returned to the host. Another possible error would be if the host is late in supplying data. If this occurs, the controller writes

an IRG, stops the drive, and returns the appropriate Data-Underrun result code.

The READ-a-block command also provides error checking. Once this command is issued by the host, the controller checks for cassette presence. If present, it starts the transport. The data output from the transport is then examined and decoded continuously. If the first character is not a SYNC, that's an error and the controller returns a Bad-First-SYNC result code (42H) after advancing to the next IRG. If the SYNC is good, the succeeding characters are read into an on-chip 30 character circular buffer. This continues until an IRG is encountered. When this occurs, the transport is stopped. The controller then tests that the last character. If it is a SYNC, the controller then compares the accumulated internal checksum to the block's checksum, the second to the last character of the block. If they match, a Good-Completion result code (00H) is returned to the host. If either test is bad, the appropriate error result code is returned. The READ command also checks for the End-of-Tape (EOT) clear leader and returns the appropriate error result code if it is found before the read operation is complete. This gold and its not transmit

The 30 character circular buffer allows the host up to 30 character times of response time before the host must collect the data. All data transfers take place thru the UPI-41A Data Bus Buffer Output register (DBBOUT). The controller continually monitors the status of this register and moves characters from the circular buffer to the register whenever it is empty.

The SKIP-n-blocks command allows the host to skip the transport forward or backward up to 127 blocks. Once the command is issued, the controller expects one data byte specifying the number of

2-49 AFN-01342A

blocks to skip. The most significant bit of this byte selects the direction of the skip (0=forward, 1=reverse). SKIP is a dual-speed operation in the forward direction. If the number of blocks to skip is greater than 8, the controller uses fast-forward (5 IPS) until it is within 8 blocks of the desired location. Once within 8 blocks, the controller switches to the normal read speed (3 IPS) to allow accurate placement of the tape. The reverse skip uses only the rewind speed (15 IPS). Like the READ and WRITE commands, SKIP also checks for EOT and beginning-of-tape (BOT) depending upon the tape's direction. An error result code is returned if either is encountered before the number of blocks skipped is complete.

The REWIND command simply rewinds the tape to the BOT clear leader. The ABORT command allows the termination of any operation in progress, except a REWIND. All commands, including ABORT, always leave the tape positioned on an IRG.

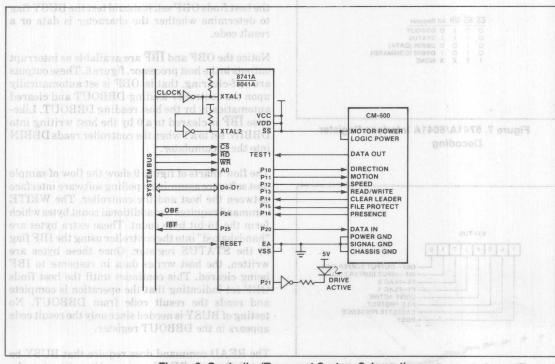

# THE HARDWARE INTERFACE IS A MILE OF THE MILE OF THE HARDWARE INTERFACE IS A MILE OF THE MILE OF THE MI

There's hardly any hardware design effort required for the controller and transport interface in figure 6. Since the CM-600 is TTL compatible, it connects

directly to the I/O ports of the UPI controller. If the two are separated (i.e. on different PC cards), it is recommended that TTL buffers be provided.) The only external circuitry needed is an LED driver for the DRIVE ACTIVE status indicator.

The 8741A-to-host interface is equally straightforward. It has a standard asynchronous peripheral interface: 8 data lines ( $D_0$ - $D_7$ ), read (RD), write (WR), register select (AO), and chip select (CS). Thus it connects directly to an 8086, 8088, 8085A, 8080, or 8048 bus structure. Two interrupt outputs are provided for data transfer requests if the particular system is interrupt-driven. DMA transfer capability is also available. The clock input can be driven from a crystal directly or with the system clock (6MHz max). The UPI-41A clock may be asynchronous with respect to other clocks within the system.

This application was developed on an Intel iSBC 80/30 single board computer. The iSBC 80/30 is controlled by an 8085A microprocessor, contains 16K bytes of dual-ported dynamic RAM and up to 8K bytes of either EPROM or ROM. Its I/O complement consists of an 8255A Programmable Parallel Interface, an 8251A Programmable Communica-

onti affilia de la communitation (Figure 6. Controller/Transport System Schematic along Reliant Bennit

tions Interface, an 8253 Programmable Interval Timer, and an 8259A Programmable Interrupt Controller. The iSBC 80/30 is especially convenient for UPI development since it contains an uncommitted socket dedicated to either an 8041A or 8741A, complete with buffering for its I/O ports. The iSBC 80/30 to 8741A interface is reflected in figure 8. (Optionally, an iSBC 569 Digital Controller board could be used. The iSBC 569 board contains three uncommitted UPI sockets with an interface similar to that in figure 8.)

Looking at the host-to-controller interface, the host sees the 8741A as three registers in the host's I/O address space: the data register, the command register, and the status register. The decoding of these registers is shown in figure 7. All data and commands for the controller are written into the Data Bus Buffer Input register (DBBIN). The state of the register select input. AO, determines whether a command or data is written. (Writes with AO set to 1 are commands by convention.) All data and results from the controller are read by the host from the Data Bus Buffer Output register (DBBOUT).

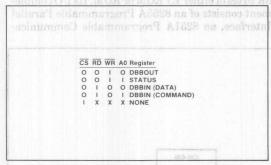

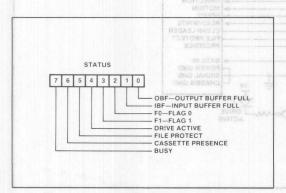

Figure 7. 8741A/8041A Interface Register Decoding

The Status register contains flags which give the host the status of various operations within the controller. Its format is given in figure 8. The Input Buffer Full (IBF) and Output Buffer Full (OBF) flags show the Status of the DBBIN and DBBOUT registers respectively. IBF indicates when the DBBIN register contains data written by the host. The host may write to DBBIN only when IBF is 0. Likewise, the host may read DBBOUT only when OBF is set to a 1. These bits are handled automatically by the UPI-41A internal hardware. FLAG 0 (F<sub>0</sub>) and FLAG 1 (F<sub>1</sub>) are general purpose flags used internally by the controller which have no meaning externally, a groted because one at realities

The remaining four bits are user-definable. For this application they are DRIVE ACTIVE, FILE PRO-TECT, CASSETTE PRESENCE, and BUSY flags. The FILE PROTECT and CASSETTE PRESENCE flags reflect the state of the corresponding I/O lines from the transport. DRIVE ACTIVE is set whenever the transport motor is on and the controller is performing an operation. The BUSY flag indicates whether the contents of the DBBOUT register is data or a result code. The BUSY flag is set whenever a command is issued by the host and accepted by the controller. As long as BUSY is set, any character found in DBBOUT is a result code. Thus whenever the host finds OBF set, it should test the BUSY flag to determine whether the character is data or a result code.

Notice the OBF and IBF are available as interrupt outputs to the host processor, figure 6. These outputs are self-clearing, that is, OBF is set automatically upon the controller loading DBBOUT and cleared automatically by the host reading DBBOUT, Likewise IBF is cleared to a 0 by the host writing into DBBIN: set to a 1 when the controller reads DBBIN into the accumulator.

The flow charts of figure 9 show the flow of sample host software assuming a polling software interface between the host and the controller. The WRITE command requires two additional count bytes which form the 16-bit byte count. These extra bytes are "handshaked" into the controller using the IBF flag in the STATUS register. Once these bytes are written, the host writes data in response to IBF being cleared. This continues until the host finds OBF set indicating that the operation is complete and reads the result code from DBBOUT. No testing of BUSY is needed since only the result code appears in the DBBOUT register.

The READ command does require that BUSY be Figure 8. Status Register Bit Definition tested. Once the READ command is written into the

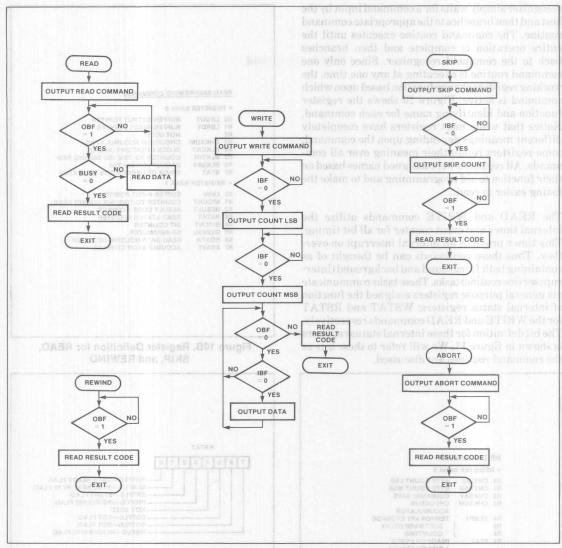

Figure 9. Host CPU Flow Charts for Commands When Polling is Used

controller, the host must test BUSY whenever OBF is set to determine whether the contents of DBBOUT is data from the tape or the result code.

The SKIP command requires the skip count byte. This byte is written into DBBIN after IBF has been cleared following the command. The host then waits until OBF is set indicating the operation is complete and the result code is waiting in DBBOUT. The REWIND and ABORT commands only require that the host test OBF. Once set, the result code is ready in DBBOUT.

The flow charts for an interrupt-driven system are simplified since no testing of OBF or IBF is required. The mere fact that an interrupt occurred implies that the corresponding bit in the STATUS REGISTER is set or cleared.

#### THE CONTROLLER SOFTWARE

The internal UPI-41A software can be divided roughly into the various commands. (This software is discussed as flow charts. The actual program listing is included in Appendix A.) A command

recognizer simply waits for a command input by the host and then branches to the appropriate command routine. The command routine executes until the entire operation is complete and then branches back to the command recognizer. Since only one command routine is executing at any one time, the working registers change function based upon which command is active. Figure 10 shows the register function and identifying name for each command. Notice that while most registers have completely different meanings depending upon the command, some registers retain their meaning over all commands. All registers were assigned names based on their function to aid programming and to make the listing easier to read.

The READ and WRITE commands utilize the internal timer and event counter for all bit timing. This timer provides an internal interrupt on overflow. Thus these commands can be thought of as containing both foreground and background (interrupt service routine) tasks. These tasks communicate via general purpose registers assigned the function of internal status registers: WSTAT and RSTAT for the WRITE and READ commands respectively. The bit definition for these internal status registers is shown in figure 11. We will refer to these bits as the command routines are discussed.

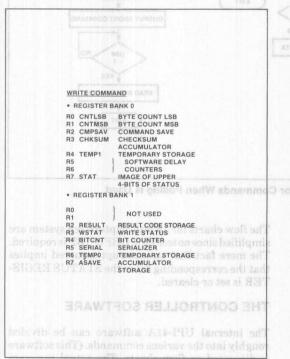

Figure 10A. Register Definition for WRITE

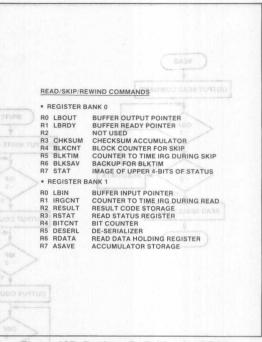

Figure 10B. Register Definition for READ, SKIP, and REWIND

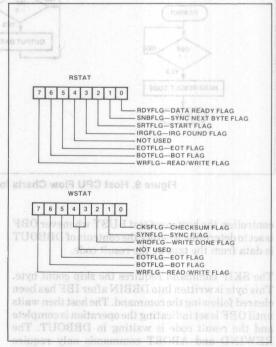

Figure 11. READ and WRITE Internal Status Register Bit Definitions

#### WRITE COMMAND

Let's look at the WRITE command routine first, figure 12. As was mentioned earlier, the WRITE requires two additional data bytes before it can be processed. Once the command recognizer branches to the WRITE routine, the routine waits on IBF until these bytes are written by the host. These count bytes are stored in the CNTLSB and CNTMSB (Count Least and Most Significant Byte) registers. These two registers are concatenated to form the 16-bit byte count. At this point, the routine tests the

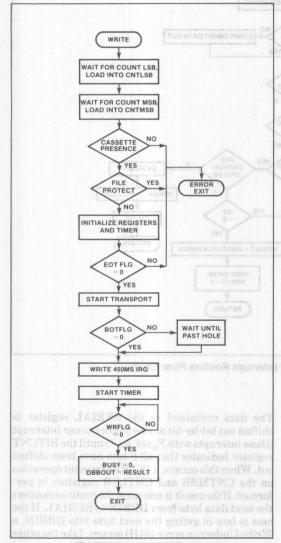

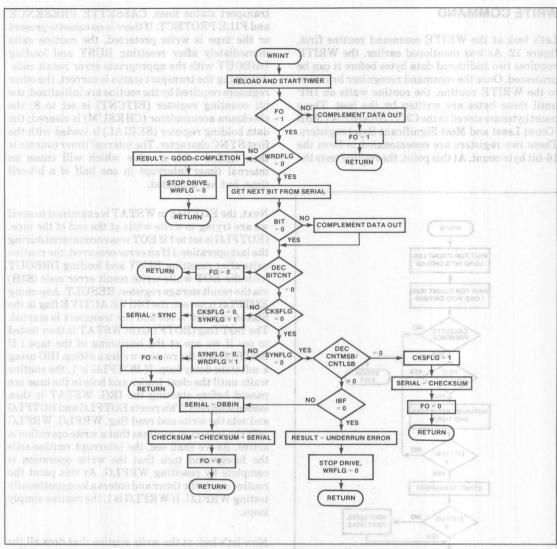

Figure 12. WRITE Command Flow Chart

transport status lines, CASSETTE PRESENCE and FILE PROTECT. If there is no cassette present or the tape is write protected, the routine exits immediately after resetting BUSY and loading DBBOUT with the appropriate error result code Assuming the transport status is correct, the other registers required by the routine are initialized: the bit counting register (BITCNT) is set to 8; the checksum accumulator (CHKSUM) is cleared; the data holding register (SERIAL) is loaded with the first SYNC character. The internal timer counter is then loaded with a value which will cause an internal timer interrupt in one half of a bit-cell time, but not activated.

Next, the EOT flag in WSTAT is examined to see if we are trying to write while at the end of the tape. (EOTFLG is set to 1 if EOT was encountered during the last operation.) If an error occurred, the routine exits after resetting BUSY and loading DBBOUT with the EOT-while-write result error code (83H) via the result storage register, RESULT. Assuming EOTFLG is not set, the DRIVE ACTIVE flag in the Status register is set and the transport is started. The BOT flag (BOTFLG) in WSTAT is then tested to see if we are at the beginning of the tape.) If BOTFLG is 0, the routine writes a 450ms IRG using a software delay loop. If BOTFLG is 1, the routine waits until the clear leader and hole in the tape are passed before starting the IRG. WSTAT is then loaded with 80H. This resets EOTFLG and BOTFLG and sets the write and read flag, WRFLG. WRFLG tells the interrupt routines that a write operation is active. As we shall see, the interrupt routine tells the foreground task that the write operation is complete by resetting WRFLG. At this point the routine starts the timer and enters a loop continually testing WRFLG. If WRFLG is 1, the routine simply loops.

Now let's look at the write routine that does all the work: the write timer interrupt service routine. When the timer interrupt occurs half a bit-cell time later, an automatic vector to the INT routine is performed (location 07H in program memory). INT test WRFLG to see whether it's a read or write operation in progress and branches accordingly. Since we are talking about a write operation, the branch is to the WRINT routine, figure 13. WRINT first reloads the timer to provide the timing for the next half cell (the timer continues to run). The Fo is used to define whether this particular interrupt is for the first or the second half of the bit cell. The phase encoding algorithm used specifies that the beginning of a bit must always have a transition. If Fo is reset, the data output to the transport is simply

SHIPPOT SOLVED JOURN Figure 13. WRINT—Write Timer Interrupt Routine Flow Chart

complemented providing the transition. If set, the interrupt is at the mid-cell position. If the data bit is a 1, complement the data output; otherwise, do not change it.  $F_0$  is complemented every interrupt.

The CLEAR LEADER input from the transport is also tested on every interrupt. If it was encountered, the transport is stopped, the EOTFLG in WSTAT is set, WRFLG is reset, and RESULT is loaded with the EOT-while-write error result code (83H). WRINT returns to the main write loop.

The data contained in the SERIAL register is shifted out bit-by-bit at every other timer interrupt (those interupts with  $F_0$  set to a 1) until the BITCNT register indicates that all 8 bits have been shifted out. When this occurs, a 16-bit decrement operation on the CNTMSB and CNTLSB registers is performed. If the result is non-zero, the routine transfers the next data byte from DBBIN to SERIAL. If the host is late in geting the next byte into DBBIN, a Write-Underrun error (81H) occurs. Like the other error conditions, WRFLG in WSTAT is reset and

the Write-Underrun error result code is loaded into the result holding register, RESULT, before returning to the main write loop. If the data is ready in DBBIN, it is transferred to SERIAL and added to the accumulating checksum. The routine then returns to the write main foreground task. (Remember that the foreground task is doing nothing more than testing WRFLG.)

If the decrement result is zero, all data transfers are complete. The accumulated checksum value is loaded into Serial and the Checksum flag, CKSFLG, is set in WSTAT before exiting the interrupt routine. This causes the checksum value to be written onto the tape. Sixteen timer interrupts later the checksum is complete; it is now time to write the final SYNC. CKSFLG is reset, a SYNC character is loaded into SERIAL, and the SYNC flag (SYNFLG), is set in WSTAT. Sixteen more timer interrupts later the SYNC is written to the tape and the block is almost finished. One more interrupt is needed to finish the last bit. The write done flag (WRDFLG) is set to indicate that this is the last interrupt for this block. WRDFLG is detected as being set to a 1 on the next interrupt and the transport is stopped. WRFLG in WSTAT is reset and the Good-Completion result code is loaded into the RESULT register before exiting to the foreground task.

All this occurs while the foreground task is testing WRFLG. When WRFLG is cleared, the foreground task "knows" that the background task is finished: BUSY is reset and the result code stored in RESULT is loaded into DBBOUT. The program then returns to the command recognizer.

#### READ OPERATION

In the case of the read command, figure 14, the RSTAT register provides the communication between the foreground and background tasks. The read command routine starts out by initializing the registers it requires: the checksum accumulator, CHKSUUM, is cleared; pointers for the circular buffer, DBIN, LBRDY, and LBOUT are set to the start of the buffer; and the bit counter, BITCNT, is set to 8.

The circular buffer has three pointers: LBIN to point to the next free buffer location, LBOUT to point to the next location from which to retrieve data, and LDRTDY to trail LBIN by two locations. LBRDY trails LBIN to ensure that the host does not get the received checksum or last SYNC bytes as data. The buffer is empty whenever LDRDY equals LBOUT. The buffer is full whenever LBOUT minus

loading it into the location pointed at by LBIN and then LBIN is incremented. Data is removed from the buffer at the location pointed at by LBOUT and the LBOUT is incrementd by one. The data memory locations 20H thru 3FH form the circular buffer. Any pointer increment or decrement operation limits the pointers to this range. (If a pointer at 3FH is incremented, the result wraps around to 20H.)

Once the registers have been initialized, the timer is loaded, but not started, with a value that corresponds to 3/4 of a bit-cell time. Next, the EOT test is performed on the EOTFLG in RSTAT. The routine exits with an EOT-while-read error result code if an attempt to read is made while at EOT. If not, the transport is started and the BOTFLG is tested to see if it must move past the clear leader and hole. Once past the clear leader and hole, if necessary, the SYNC-Next-Byte flag (SNBFLG), and the Start flag (SRTFLG), are set in RSTAT. SNBFLG informs the software that the next received byte should be a SYNC. SRTFLG prevents LBRDY from being incremented prematurely.

As soon as a transition from mark (1) to space (0) is detected, the timer is started. The routine enters a loop which tests the data ready flag (RDYFLG), the IRG found flag (IRGFLG), and the EOT detected flag (EOTFLG) in RSTAT. These flags are set by the background task to communicate with the foreground. RDYFLG is set when a character has been assembled and is waiting in the holding register, RDATA. IRGFLG is set when an IRG has been found by the background task. EOTFLG has the same meaning as with the write command; the clear leader at the end of the tape has been found.

If none of these flags are set, the foreground then looks at the circular buffer to see if it contains any data to output to the host. The buffer contains data when LBIN does not equal LBOUT. If these pointers are equal, the buffer is empty and the foreground task just continues to loop. If they are not equal, there is some data left in the buffer. OBF is tested to see if DBBOUT is free to accept more data. If it is free, the character pointed at by LBOUT is transfered to DBBOUT and LBOUT is incremented to the next location. If DBBOUT still contains previously loaded data (OBF set), the foreground continues to test the flags in RSTAT.

When the foreground task finds RDYFLG set, data is available in RDATA. Before transfering this data into the buffer, it first compares LBIN and LBOUT. If LBOUT is one less than LBIN, the buffer is full and no more data can be loaded. This is an error 1 equals LBIN. Data is placed in the buffer by condition; the read operation is aborted and the

> 2-56 AFN-01342A

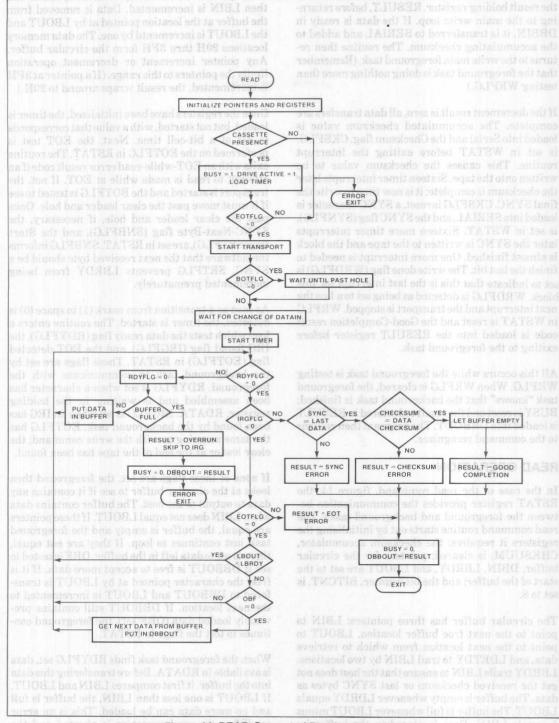

Figure 14. READ Command Routine Flow Chart

transport is moved to the next IRG using the SKIP routine discussed below. Once at the next IRG. BUSY is reset and the Read-Overrun error result. code (41H) is placed in DBBOUT. This terminates the read operation and the routine branches back to the command recognizer. Tol supindost smas adT SKIP command routine. The SKIP command, figure

If the buffer is not full, the data is transfered from RDATA to the location pointed to by LBIN, LBIN is incremented and the RDYFLG in RSTAT is reset. LBRDY is also incremented if LBIN has been incremented twice already. (SRTFLG set prevents LBRDY from being incremented. SRTFLG is reset when LBIN is incremented to the second buffer position.) This ensures that LBRDY will point to the last data byte once an IRG is detected. The data is also added to the accumulated checksum, CHKSUM. The foreground then goes back to test the RSTAT flags. When IRGFLG is found set, the background task has found an IRG and stopped the transport. This indicates that the block read is complete. Since the IRG occurs after the checksum and final SYNC characters, these two bytes are in the circular buffer. To test them the foreground task then decrements LBIN to point at the final SYNC and checks if it is a SYNC character. If not, a Bad-Sync2 error result code (43H) is placed in RESULT and the routine branches to the read exit routine. If it is okay, a SYNC is removed from the accumulated checksum. LBIN is decremented again to point to the received checksum. Since this character is also in the accumulated checksum, it is subtracted out. Now the accumulated checksum reflects only the received data so it is compared with the received checksum. If they are equal, the data is presumed good and a Good-Completion result code (00H) is loaded into result. If not, an error has occured and the RESULT is loaded with the Bad-Checksum result code (44H).

Although the actual read operation is complete with respect to the transport, there may still be data remaining in the buffer of the controller. The read exit routine loops testing LBOUT and LBRDY and transfering data from the buffer into DBBOUT until the buffer is empty. Once the buffer is empty. BUSY is reset and the result code is transferred from RESULT to DBBOUT, completing the read operation.

The timer interrupt routine, RDINT, for the read operation is shown in figure 15. The phase decoding algorithm specifies that the timer start at the beginning transition of the bit cell. It waits for 3/4 of a bit cell before sampling the data input. If the data input is the same as immediately after the beginning transition, the data bit is a 0. If it is different, the same of the Routine Flow Chart

data bit is a 1. The timer interrupt routine compares the present state of the data input to the state immediately following the beginning transition. Fo stores this value and shifts it into the de-serializing register (DESERL), Once 8 bits have been accumulated, the RDYFLG is set to inform the foreground that a character is complete. This character is then transfered from DESERL to the holding register. RDATA

After the interrupt routine has sampled and shifted in the bit, it looks for the beginning transition of the

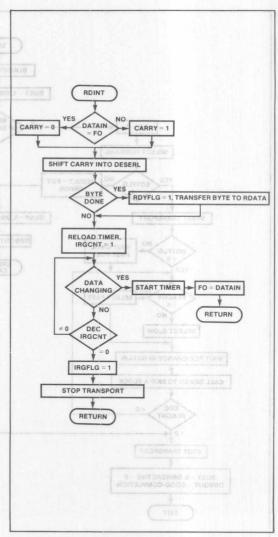

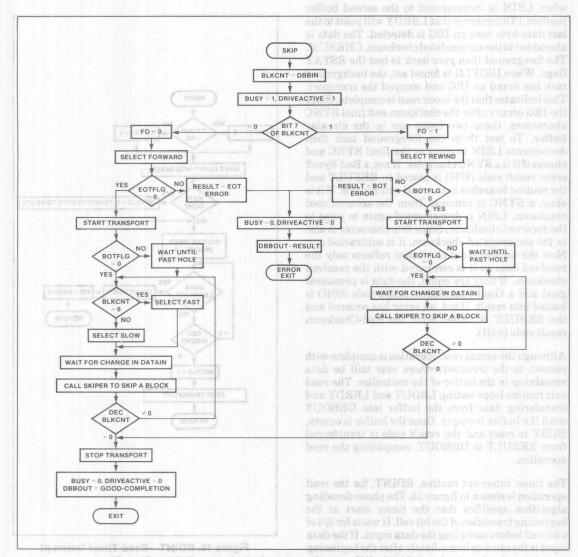

Figure 15. RDINT—Read Timer Interrupt

next bit cell. While looking for this transition, it keeps track of time be decrementing a counter called IRGCNT. If this counter reaches zero, no transition has occured within a certain amount of time (this application used two bit cell times); this is defined as the beginning of an IRG. When an IRG is found, the transport is stopped and the IRGFLG is set in RSTAT before exiting the interrupt service routine. If a transition is found before the counter times out, the routine exits setting  $\mathbf{F}_0$  to the data input state after the transition.  $\mathbf{F}_0$  is used for storing the state while in the foreground. As in the write operation, the CLEAR LEADER input is also

tested every interrupt. If an EOT is found, EOTFLG is set and the transport is stopped.

# SKIP OPERATION (MCI H) handle at (H.14) aboo

The same technique for finding IRGs is used in the SKIP command, figure 16, causes the transport to skip forward or reverse a specified number of IRGs. The number of IRGs to skip is indicated by the byte following the SKIP command byte acceptance (i.e. BUSY has been set and IBF is 0). The SKIP command routine waits, looping on IBF, until the IRG skip count is loaded by

restO wolld and Figure 16. SKIP Command Routine Flow Chart 0 s at the also end, mentioned

APPI ICATIONS

BOI tests are performed to ensure it doesn't skip forward when at EOT or reverse when at BOT. The transport is then started in the direction indicated by bit 7 of the BLKCNT value. (This bit is masked off after the initial direction test.)

For reverse skips, the skipping subroutine, SKIPER, is called. It advances the transport to the next IRG using the IRGCNT technique described above. When SKIPER returns, BLKCNT is decremented and tested for zero. If non-zero, SKIPER is called repeatedly until BLKCNT is zero. Once zero, the transport is stopped and BUSY is reset. DBBOUT is loaded with a Good-Completion result code (00H).

When doing forward skips, the software takes advantage of the fact that the transport can recognize IRGs during fast forward. If the BLKCNT is greater than 8, fast forward is selected instead of slow and SKIPER is called. (The IRGCNT value is modified to take into account the faster tape speed.) When SKIPER returns, BLKCNT is decremented and tested both for being less than 8 or equal to zero. Once BLKCNT is less than 8, the slow speed is selected. Once BLKCNT reaches 0, the operation is terminated like the reverse skips. The transport is stopped and BUSY is cleared. DBBOUT is loaded with a Good-Completion result code.

As with both READ and WRITE commands, the clear leader test is made periodically to ensure that no skips are made past the end or beginning of the tape. The appropriate error result code is issued if CLEAR LEADER is found set. RSTAT is loaded with the appropriate EOTFLG bit set.

#### **REWIND OPERATION**

The REWIND command routine, figure 17, simply sets the transport to fast rewind and loops until clear leader is found for greater than 50ms. (The hole at the ends of the tape is guaranteed not to cause the clear leader input to be active for more than 50ms.) Once the tape's clear leader is found; the transport is stopped; BUSY is reset. A Good-Completion result code is loaded into DBBOUT. Also, since the transport is now at the BOT, the BOTFLG is RSTAT is set.

#### **ABORT OPERATION**

The final command is the ABORT command. It does not have a separate flow chart of its own. All other commands monitor IBF periodically during

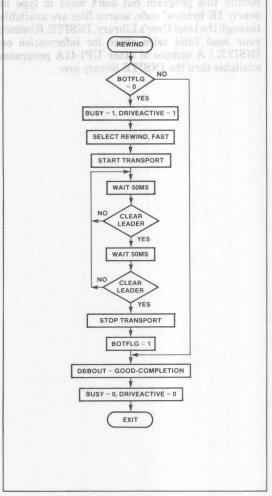

Figure 17. REWIND Command Routine Flow Chart

their execution. If a command is found, the command is compared to the ABORT command code. If it is found, the routine in execution is stopped and BUSY is reset. The Abort-Complete result code is placed in DBBOUT. The aborted routine does ensure that it exits gracefully. An aborted READ or SKIP advances to the next IRG before stopping; WRITE records an IRG before stopping.

#### WRAPPING IT UP

The program listing follows in Appendix A. For more information on the UPI-41A family, see the

Selko printer controller
Olivetti printer controller
LRC printer controller (8295)
Sensor matrix controller
LED display controller
Combination serial/parallel I/O
Programmable keyboard/display controller
GPIB controller (8292)

For reverse skips, the skipping subroutine, SKIPER, is called. It advances the transport to the next IRG using the IRGCNT technique described above. When SKIPER returns, BLKCNT is decremented and tested for zero. If non-zero, SKIPER is called repeatedly until BLKCNT is zero. Once zero, the transport is stopped and BUSY is reset. DBBOUT is loaded with a Good-Completion result code (00H).

When doing forward skips, the software takes advantage of the fact that the transport can recognize IRGs during fast forward. If the BLKCNT is greater than 8, fast forward is selected instead of stoward is selected instead of solve and SKIPER is called. (The IRGCNT value is modified to take into account the faster tape speed.) When SKIPER returns, BLKCNT is decremented and tested both for being less than 8 or equal to zero. Once BLKCNT is less than 8, the slow speed is selected. Once BLKCNT reaches 0, the operation is berminated like the reverse skips. The transport is stopped and BUSY is cleared. DBBOUT is loaded with a Good-Corolletion result code.

As with both READ and WRITE commands, the clear leader test is made periodically to ensure that no slops are made past the end or beginning of the tape. The appropriate error result code is issued if CLEAR LEADER is found set. RSTAT is loaded with the appropriate EOTFLG bit set.

#### REWIND OPERATION

The REWIND command routine, figure 17, simply sets the transport to fast rewind and loops until clear leader is found for greater than 50ms. (The hole at the ends of the tape is guaranteed not to cause the clear leader input to be active for more than 50ms.) Once the tape's clear leader is found; the transport is stopped; BUSY is reset. A Good-Completion result code is loaded into DEBOUT. Also, since the transport is now at the BOT, the BOTFIG is RESTAT is set.

#### MOSTAGRIO TROPA

The final command is the ABORT command. It does not have a separate flow chart of its own. All other commands monitor IBF periodically during

referenced manuals on the cover of this application note. For those readers who would like to use or modify this program but don't want to type in nearly 1K bytes of code, source files are available through the Intel User's Library, INSITE. (Contact your local Intel sales office for information on INSITE.) A sample of other UPI-41A programs available thru the INSITE library are:

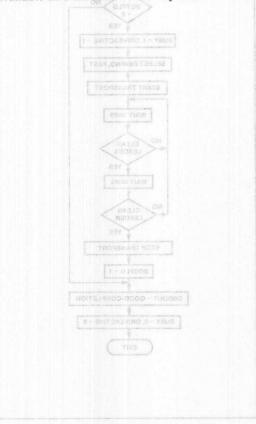

Figure 17. REWIND Command Routine Flow Chart

their execution. If a command is found, the command is compared to the ABORT command code. If it is found, the routine in execution is stopped and BUSY is reset. The Abort-Complete result code is placed in DBBOUT. The aborted routine does ensure that it exits gracefully. An aborted READ or SKIP advances to the next IRG before stopping; WRITE records an IRG before stopping.

#### WEAPPING IT UP

The program listing follows in Appendix A. For more information on the UPI-41A family, see the

#### INTRODUCTION

Many microprocessor systems require the real-time control of a peripheral device such as a printer, keyboard, or alpha-numeric display, etc. These medium speed but still real-time tasks can be rather mundane, time-consuming, and require a fair amount of system software overhead. Of course, any time spent by the main processor in servicing these I/O devices is unavailable for other, possibly more important, tasks. This processor burden can largely be removed by isolating the real-time portion of the task to a dedicated peripheral-control processer.

Until recently, this approach was usually not cost effective due to the large number of components required by the dedicated processor: CPU, RAM, ROM, I/O, etc. To help make the approach more cost effective, Intel borrowed the I/O processing concepts found in many mainframe and minicomputers; put all the hardware in one package; and introduced a family of Universal Peripheral Interface controllers—the UPI-41ATM family. The basic family consists of the 8041A and the 8741A. These two devices are essentially single-chip microcomputers with a standard microprocessor bus interface. They have onchip RAM, ROM (8041A) or EPROM (8741A), CPU, timer/counter, and I/O. Using one of the UPI family, the designer simply codes his custom or proprietary peripheral control algorithm into the UPI device itself rather than the main system software. The UPI device then takes over the peripheral control task while the host processor simply issues commands and transfers data. More information on the UPI family is available in the documents referenced opposite the table of contents.

Illustrating the UPI concept as both design examples and actual products, a number of pre-programmed 8041As are available. These devices are the 8278 Keyboard/Display Controller, the 8294 Data Encryption Unit, the 8292 GPIB Controller, and the 8295 Dot Matrix Printer Controller. Data sheets for these devices are found in the Peripheral Design Handbook and their source listings (except for the 8294) are available in Insite, Intel's User's library. This application note deals with the 8295.

#### **THE 8295**

The 8295 Dot Matrix Printer Controller is a device specifically designed to interface microprocessors to the LRC 7040 Series of dot matrix impact printers. It offers complete solenoid and motor drive timing and contains an on-chip 7×7 character generator accommodating 64 ASCII characters. An on-chip FIFO buffers up to 40 ASCII characters before printing. Character density, width, and print intensity are all programmable. Three programmable tabulations and two general purpose outputs are also provided. Four data transfer methods are possible: polling, interrupt-driven, and Direct Memory

Access (DMA) are available when in parallel data transfer mode and asynchronous serial is available in serial mode. The data transfer mode is hardware selectable.

Let's first look at the LRC printer itself and its interface to the 8295.

# THE LRC 7040 PRINTER OF SIRINGOINGER SE Abionsion

The LRC Model 7040 printer is manufactured by LRC, Inc. of Riverton, Wyoming. Capable of printing 40 columns of characters at a speed of 1.25 lines/sec, the 7040 is mechanically simple and is ideal for point-of-sale or data logging terminals.

It is an impact printer whose print head consists of seven solenoids which each drives a stiff wire to impact the paper through an inked ribbon. While the wires are arranged in a circular fashion at the solenoid end, they form a vertical column at the ribbon impact point, Characters are formed by firing the solenoids to form a  $5\times7$  or  $7\times7$  matrix of "dots" (impacts of the wires). Figure 1 shows how the character A is formed using a  $7\times7$  matrix. The columns are labeled C1 thru C7 and the rows R1 thru R7. The print head moves left to right across the paper so at time T1, the head is over column C1. If the correct solenoids are activated at each time Tx for each column Cx, the character is formed.

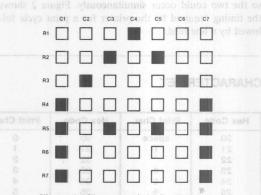

Figure 1. Character A in 7×7 Format

The print head is moved across the paper by the main motor drive. The main motor drive consists of a 24-pole synchronous motor which drives a rotating plastic drum. The drum has a spiral groove molded into it and a pin on the print head rests in the groove so that the print head traverses the paper as the drum rotates. Characters are printed by firing the solenoids during the left-to-right traverse. At the end of the print area, the spiral groove reverses the direction of the print head returning it to its home position.

A HOME microswitch riding on a cam attached to the plastic drum provides the only feedback as to the print head position. When the print head is in its home resting position the HOME switch is inactive. To start a print cycle, the main motor drive is activated which starts the print head motion. As the print head reaches the beginning of the print area, the cam activates the HOME switch as a signal to the printer controller to commence firing the solenoids. The controller then activates the solenoids as appropriate for each character in the line. The print area is defined as the 310ms immediately after HOME goes active. Solenoid timing is the responsibility of the controller; the printer mechanism supplies no character-position information.

After the line is printed and the print head has traversed right to left, the HOME switch is deactivated. This transition signals the controller to turn off the main motor drive since the home position has been reached. A new print cycle may start immediately if data is ready.

Paper feed is accomplished with a second synchronous motor and a PFEED (Paper Feed) microswitch. In the quiescent state, the PFEED switch is inactive. Activating the paper feed motor drive starts the line feed cycle. The switch becomes active at some point during the cycle (typically about 48ms later) and is deactivated when the cycle is complete. The controller uses the active-to-inactive transition to remove the paper feed motor drive. The paper feed operation is independent of the print cycle so the two could occur simultaneously. Figure 2 shows the timing required by the printer for a print cycle followed by a line feed.

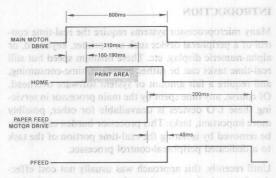

Figure 2. LRC 7040 Motor Drive Timing

Solenoid timing determines the location of any given "dot" and its intensity. The LRC 7040 printer specification states a 400 µs maximum solenoid "ON" time and a 1.3ms typical period. Since the print area is 310ms "long," this timing allows a total of 240 dots (310ms/1.3ms per dot) in one row or 40 characters on a 5 × 7 matrix with a one dot space between characters. While  $5 \times 7$  characters have acceptable readability, their distinctness and format can be improved with a  $7 \times 7$  matrix, however, 40  $7 \times 7$ characters translate to 320 dots per row or a 0.97ms solenoid period. This violates the solenoid duty cycle spec if the solenoids are fired for every column. The best way to get around this dilemma and still retain the improved readability of the  $7 \times 7$  format is to simply fire the solenoid every other column. The 8295 uses this technique and the "every-other" column spacing is reflected in Figure 1. The 8295 character set is included in Figure 3.

width, and print intensity are all programmable. Three

#### 8295/Printer Interface

It's the job of the 8295/Printer interface to convert the TTL-compatible outputs of the 8295 to the motor and solenoid drive levels. Since the printer side of the 8295 is independent of the system side, this same 8295/Printer interface is used for all examples discussed in the later sections.

For solenoid drive, the 8295 supplies seven solenoid outputs,  $\overline{S1}$  thru  $\overline{S7}$ , plus a solenoid strobe, STB. STB modulates the SI-S7 outputs externally to supply the actual solenoid "ON" time. This time is software programmable. Figure 4 shows the recommended SI-S7/STB gating.

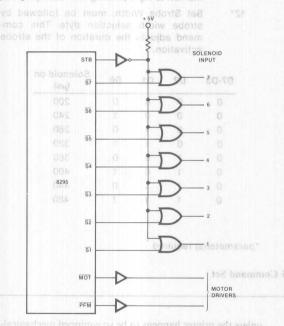

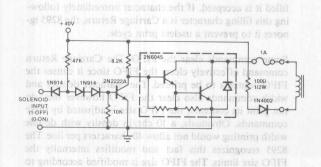

Figure 4. Solenoid and Motor Gating

sidsming && vin Figure 5. Solenoid Driveria dibiw signiz

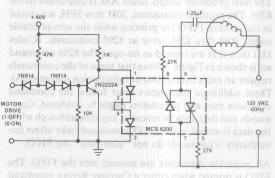

The solenoids must be driven from a  $40^{\circ} \pm 10\%$  volt source. The peak current is approximately 3.6A, the average current is approximately 0.5A. A circuit providing the required drive is shown in Figure 5. The output stage, consisting of the 2N6045 Darlington transistor, the 1N4002 catching diode, and the 100-ohm damping resistor, is the one suggested by the manufacturer. The input stage is a discrete implementation of a DTL gate. Note that the base-emitter junction of the 2N6045 protects the 2N2222A transistor from overvoltage on its collector. This circuit has several features which are important to the printer interface:

- 1.4 All solenoid power (including the power used to drive as the base of the power transistor) is derived from the 40-volt supply.
- 2. Disconnecting the drivers from the 8295 or the loss of the 5-volt supply to the 8295 results in the solenoids turning off,

The first feature of the drivers minimizes the impact of the printer and its interface on the 5-volt supply. The second feature prevents the activation of the solenoids erroneously during power on/off cycles or during system checkout. This an important point since the solenoids will be damaged if left activated continuously. The fuses is series with the solenoids help protect them from mishap.

The two motors can each be driven as shown in Figure 6. The Monsanto MCS-6200 is an optically-coupled TRIAC which is ideal for driving the small synchronous motors in the printer. Coupled with a buffer this part provides a simple means of controlling the motors without sacrificing the isolation required for safe and reliable operation.

These driver circuits were borrowed from the Intel application note AP-27 "Printer Control With the UPI-41." (The 8295 development was inspired by the success of the AP-27 design.) Other solenoid and motor driver circuits are described in the LRC Interface Guide available from the manufacturer.

Figure 7. 8295 Command Set

#### 8295 Command Software

The software control of the 8295 is very straightforward. The host processor simply issues ASCII characters to the 8295. The printable characters, 20H thru 5FH, are stored in the on-chip FIFO for printing while the non-printable codes, 00H thru 12H, serve as 8295 commands. (Codes 13H thru 1FH are treated as no-ops.) The 8295 command set is shown in Figure 7. Note that some of the commands require an extra byte or two of information (parameters). These additional parameters must follow the command otherwise data and parameters might be confused. Commands and data may be mixed at any time although while the data is stored in the FIFO, commands take effect immediately. Commands do not "pass-thru" the FIFO.

All printable characters are entered into the FIFO. The FIFO is printed when either a Carriage Return command is received or the FIFO becomes full. In either case, the FIFO is printed, however there is no automatic line feed

unless the printer happens to be so equipped mechanically. Thus, a Line Feed command should be issued after each Carriage Return or after the last character to fill the FIFO. The FIFO is printed as soon as the character that filled it is accepted. If the character immediately following this filling character is a Carriage Return, the 8295 ignores it to prevent a useless print cycle.

Some commands clear the FIFO. The Carriage Return command effectively clears the FIFO since it causes the FIFO contents to be printed. The character density and width commands also clear the FIFO however they do not print its contents; the FIFO size is adjusted by these commands. Obviously, a 10 chr/in density with double width printing would not allow 40 characters per line. The 8295 recognizes this fact and modifies internally the FIFO size limits. The FIFO size is modified according to the table below. For example, if the density is 10 char/in, single width printing, the 8295 accepts only 33 printable

characters before starting a print cycle. Since these commands take effect as soon as they are accepted, this prevents mixing different character densities or widths on a given line. Any such commands must precede the data for a line.

The Software Reset command clears the FIFO, resets the density to 12 chr/in and selects single width printing. It does not effect the solenoid strobe width, the tab positions, or the general purpose outputs. This command should be issued only when the 8295 is expecting a command or data. Issuing it when the 8295 is expecting a parameter causes it to be interpreted as the parameter and not the intended software reset.

A hardware reset causes the 8295 to default into the following states:

- 1. Clears the FIFO of qu for wolfer allowed parameters allowed the property of the control of th
- 2. GP1 and GP2 set high
- 3. 12 chr/in density
- 4. single width prining
- 5. 320μs strobe width
- 6. tab positions indeterminate.

#### Parallel Interfaces

The 8295 has the option of using serial or parallel communication with the main processor. The choice must be

made early in the design cycle since it is a hardware, not a software, selection. Let's look at the parallel options first.

In parallel mode, the 8295 has the traditional microprocessor bus interface: data, control, etc. The parallel mode is selected by not grounding the IRQ/SER pin. To the main processor, the 8295 in parallel mode appears as two registers: the Input Data register and the Output Status register. The main processor writes commands and data into the Input Data register while it reads the 8295 status from the Output Status register.

The Output Status register format is shown in Figure 8. The Input Buffer Full bit (IBF) indicates whether the 8295 has accepted the previous command or data byte. IBF is automatically set when the host processor writes to the 8295 and it is reset when the 8295 accepts the data or command. If IBF = 1, no writes to the Input Data register are allowed. Only when IBF = 0 may a Input Data register write be done. The DMA Enable bit (DE) is set whenever the 8295 is performing DMA data transfers. When the specified number of transfers has been made, the DE bit is cleared. Since DMA cycles are usually transparent to the main processor, the DE bit tells the processor when the DMA block transfer is complete.

The processor does not always have to read the Output Status register, checking IBF, before loading the Input Data register. An interrupt output (IRQ) pin is available to interrupt the processor whenever the 8295 is ready to receive new data or commands. The fact that IRQ is set implies that IBF = 0, so it's not necessary for the processor to read the 8295 status when interrupted; it can just write the next byte.

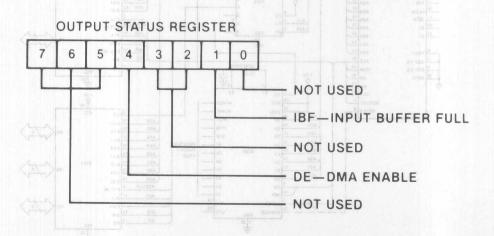

Figure 8. Output Status Register Format

Figure 9 shows the system schematic for using the 8295 in polled-parallel mode in an 8085A system; ie the IRQ line is not used. The 8085A/8295 interface is standard as for any Intel peripheral.  $\overline{CS}$  is decoded from the high-order address lines.  $\overline{RD}$  and  $\overline{WR}$  are the 8085A read and write control lines.  $\overline{RESET}$  is the system reset.

Example 8085A polling software is shown in Figure 10. This routine simply outputs the print buffer starting at the location pointed to in PRTSRT. The system software builds the buffer, terminates it with a 0FFH character, and loads PRTSRT before calling PRINT.

PRINT is not very efficient with respect to processing time. Since the 8295 does not accept data while in a print or line feed cycle, if the buffer contained more printable characters than the FIFO size, the processor would sit in the PRT2 loop during the 800ms print and 200ms line feed cycles. That is obviously not too efficient. The obvious way around this problem is to restrict the buffer size to less than that of the FIFO however this could complicate the system software since more buffer building is required. A better approach is to use interrupts.

By connecting the 8295's IRQ output to one of the 8085A RST interrupt inputs (dotted line in Figure 9), the pro-

cessor is interrupted only when the 8295 is able to take another character. Figure 11 shows such interrupt-driven software assuming the RST 6.5 interrupt input is used for IRQ.

To further enhance the bus efficiency and processor overhead at the expense of slightly more complex hardware, use the 8295 DMA interface. This DMA interface is compatible with the 8257 DMA Controller. With such an interface all that's necessary is for the processor to load the DMA Controller with the print buffer starting address and write the Enable DMA command and length parameters into the 8295. The 8295 does the rest by requesting data directly from memory thru the DMA Controller. It keeps track of the number of characters to request. As long as there are characters remaining to be transferred, the DE bit in the Output Status register is set. After the last byte is transferred into the 8295, the DE bit is reset and the IRQ is made active. Either event is used to tell the processor that DMA is complete and the 8295 is ready for the next block. It is not necessary to restrict the DMA block size to 40 characters, the Enable DMA command parameters allow for up to 65k byte block sizes. The block size given the 8295 must reflect both data plus commands and parameters.

Figure 13. 8295 DMA Subroutine

Figure 12 illustrates an 8257/8295 interface and Figure 13 shows example software for handling the system. This software assumes that the 8295 is doing the counting of the transfers hence the Terminal Count of the 8257 DMA channel is loaded with the maximum value while the 8295 receives the actual block size. The 8295 simply stops making requests once the requested number of transfers have been made.

## Serial Interface

In addition to the parallel interface options, the 8295 supports a "stand-alone" serial interface. In this mode, the only communication with the main processor is via a serial link. This configuration is perfect for remote printer applications; only three wires are required compared to 12 or 13 for the parallel interfaces.

The serial mode is envoked by simply grounding the IRQ/ $\overline{SER}$  pin. See Figure 14. The internal 8295 software interrogates this pin upon power-on and reconfigures the function of several pins if it's grounded. The  $\overline{DACK}/SIN$  pin becomes the serial data input (SIN) and the DR-Q/ $\overline{CTS}$  pin becomes the hardware data holdoff, Clear-to-Send. The lower three Data Bus pins become the Baud Rate Select inputs. Note that it is necessary to ground  $\overline{CS}$  and  $\overline{WR}$ , and pull  $\overline{RD}$  high. This enables the "input" direction of the Data Bus pins so that the 8295 may read the baud rate. All standard baud rates from 110 to 4800 baud are accommodated.

After power-on the 8295 looks at IRQ/SER and if it's grounded, the data bus pins are read to determine the baud rate. Data from the serial input is requested by lowering CTS. CTS stays low until during the eight bit of the serial data character at which point it goes high (inactive). After the character is assembled and interpreted, CTS again goes active to request the next character. The 8295 does not check for parity and characters with invalid start bits or framing errors (stop bit wrong polarity) are ignored. CTS is normally connected to the UART'S CTS input. An inactive CTS holds off the UART transmitter from transmitting characters.

In serial mode, the command and data definitions still apply as in parallel mode. Commands and data may be mixed although commands take effect immediately when received.

Figure 15 shows example software to drive an 8251A Programmable Serial Interface when connected to an 8295. This software is similar to Figure 10 except it assumes that the 8251A has the same I/O port addresses as the 8295 had in Figure 9. Note that the TXE (Transmitter Empty) flag is used to load data into the 8251A transmitting both characters in the transmitter (the transmitter is double buffered) if CTS goes inactive. The TXE flag allows only one character at a time in the transmitter so CTS going inactive simply finishes off the current character. The 8295 accepts only one character at a time.

## **8295 SOFTWARE**

For those readers using the 8295 as a design example for UPI software, the flow charts for the program are shown in Figure 16 and the 8295 source listing is included as Appendix A. (Machine readable source listings are available through Insite, the Intel User's Library.) As an aid to understanding this software, the following observations can be made:

- The 8295 uses only Register Bank 0. The function of registers R6 and R7 is determined by the mode. In parallel mode they are concantenated to form the 16 bit DMA count register. In serial mode, R6 is a counter during character reception.
- 2. Characters and commands are input from the Input Data register via the INPUT subroutine. The routine defines the input mode, fetches the data, and stores it in R2. If the DMA mode is enabled, the block count in R6 and R7 is decremented by the DECR routine each time a data transfer occurs until the count is exhausted.
- Characters are decoded by routine P6A which also detects any illegal characters by the INPUT routine.
   R0 is assigned as the character buffer pointer and R4 is designated as the buffer size limit. The commands which affect the buffer size will affect R0 and R4.

AFN-00875A

- 4. Command characters are decoded by the routine CMD. All command routines are referenced via an indirect jump table. The command routines are easy to understand from the listing hence they are not included in Figure 16 but simply referenced.
- Register R3 is the bit-oriented command register. Each bit of R3 represents an operating mode. This definition is shown below.

6. After the character buffer has reached its limit (R0=R4) or a CR character is received, the contents of the buffer are printed. Subroutine PRINT loads R0 with the address of the character to be printed and R2 serves as an index to keep track of the current column within the character. Subroutine CHAR determines which ASCII table is accessed by setting or clearing flag F0.

- 7. Subroutine XS2 multiples the least significant 5 bits of the ASCII character by 7. The result addresses one of the 32 characters on Page 1 or 2 of the Program Memory ASCII table. The column index, R2, is then added to the result to address the current column. Each character is represented by 7 bytes. R2 indexes thru each byte to select the appropriate solenoid information.
- 8. Subroutine COL8 fetches the solenoid on-time and off-time constants from a table starting at location 0F8H. The time is represented by a hex number which is used as a loop counter in a software timing loop. No character input is allowed while printing is in progress.

## CONCLUSION

The 8295 is an excellent example of what can be done with the UPI-41A family. As a printer controller, it completely relieves the main processor of all the real-time tasks associated with the control of the printer plus valuable system ROM space is not required to store the ASCII-to-dot matrix conversion table or the timing software since it's all done in the 8295 itself. As a UPI design example, the 8295 illustrates the variety of data transfer interfaces available. If the 8295 itself does not fit your printer controller requirements, feel free to modify the 8295 software contained in this application note or that in AP-27 and program your own 8741A.

Figure 16. 8295 Flow Chart

Characters and commands are input from the input Data register via the INPUT subroutine. The routine defines the input mode, fetches the data, and stores it in R2. If the DMA mode is enabled, the block count in R5 and R7 is decremented by the DECR routine cach time a data transfer occurs until the count is exhausted.

Characters are decoded by routine P6A which also detects any illegal characters by the IMPUT routine. R0 is assigned as the character buffer pointer and R4 is designated as the buffer size limit. The content and R4 is designated as the buffer size limit. The content is designated.

For those readers using the 8295 as a design example for UP1 software, the flow charts for the program are shown in Figure 16 and the 8295 source listing is included as Appendix A. (Machine readable source listings are available through Insite, the Intel User's Library.) As an aid to understanding this software, the following obser-

The 8295 uses only Register Bank 0. The function of registers R6 and R7 is determined by the mode. In parallel mode they are concamenated to form the 15 bit DMA count register. In serial mode, R6 is a counter during character reception.

## WHY DYNAMIC MEMORIES?

Dynamic RAM offers a four-to-one size advantage over their static RAM counterparts in medium to large size memory systems. In a typical 8086 system with 128K bytes of memory, you would need over 256 IC's and 300 square inches of PC board for a static memory array. The same memory array could be implemented with 68 IC's and 80 square inches of PC board if dynamic RAMs are used.

Besides this obvious size advantage, dynamic RAM designs offer a substantial power dissipation advantage. For example, the 2142 static RAM requires 0.1 mW/bit operating power, while the 2118 dynamic RAM requires only 0.01 mW/bit.

In the following sections we will show how to construct a complete dynamic memory interface for your 8086, 8088, and 8089 systems, using the 8202 dynamic RAM Controller and the 2118 5-volt only dynamic RAMs.

## TYPES OF DYNAMIC MEMORY SYSTEMS

Dynamic memory systems can be divided into two categories: 1) those that use distributed (or asynchronous) refresh and 2) those that use hidden (or synchronous) refresh. Each type has advantages over the other type; your choice will depend on your system requirements.

In a distributed refresh system the memory controller periodically requests a refresh cycle, typically every 10–16 microseconds. Since the refresh request is asynchronous to the CPU's request for the memory, the memory controller must have logic to arbitrate the requests. Once a cycle starts, the arbiter must let that cycle complete before starting a pending cycle. The memory controller should also have circuitry which can force the CPU to add WAIT state if a memory cycle is requested while a refresh cycle is in progress.

Hidden refresh designs use circuitry to monitor the CPU status lines, and request a refresh cycle when the CPU is not performing a bus cycle with the dynamic RAM. For example, a hidden refresh cycle can overlap an instruction fetch from ROM. If the hidden refresh cycles are performed frequently enough, the dynamic memory is always ready when the CPU requests a memory cycle, and no WAIT states are required due to arbitration.

Some memory systems use a combination of asynchronous and hidden refresh. For example, many real time systems allow a processor to enter a HALT state (which stops program execution) while waiting for an interrupt. During this time, the hidden refresh circuitry is inactive, and the asynchronous refresh logic inserts the necessary refresh requests. The Intel 8202 Dynamic Memory Controller provides a complete memory interface for your dynamic RAM. It can be used in synchronous and asynchronous refresh systems, and provides automatic switching between these two modes.

## 8086 SYSTEM CONFIGURATION REVIEW

## Quick Review of 8086 Family Bus Timing

There are three basic 8086 family system configurations:

- 1) Minimum Mode
- 2) Maximum Mode
- 3) Alternate Configuration

The 8086 has a  $MN/\overline{MX}$  input which can be strapped high to select Min Mode, and grounded to select Max Mode. The  $MN/\overline{MX}$  input changes the function of several other 8086 pins based on how it is strapped.

In the Min Mode, the CPU generates the  $\overline{RD}$  and  $\overline{WR}$  outputs directly. The Max Mode uses an 8288 to generate the 8202  $\overline{RD}$  and  $\overline{WR}$  signals from the CPU status lines. Refer to the "8086 Family Users Manual" for more details.

The Alternate Configuration uses several TTL gates and flip-flops and the CPU status outputs to generate the 8202  $\overline{RD}$  and  $\overline{WR}$  signals. The Alternate Configuration can be used when the CPU is strapped in either the Min Mode or the Max Mode. Each of the three basic system configurations can be used with data buffers for additional drive capability.

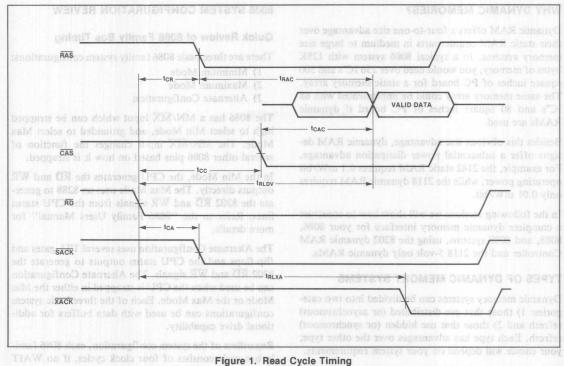

Regardless of the system configuration, each 8086 family bus cycle consists of four clock cycles, if no WAIT states are required. WAIT states can be used to extend the basic bus cycle, and thus allow the use of slower memories.

We will see in the following sections that the Min Mode will offer the lowest chip count, the Max Mode will offer better performance, while the Alternate Configuration will offer higher performance at the expense of several TTL packages.

## 8202 Read Cycle Timing

The 8202 uses its clock to sample the (asynchronous) READ requests generated by the CPU. When the RD input is sensed active, the 8202 will generate a RAS strobe and CAS strobe as shown in Figure 1. The RAM uses RAS and CAS to latch the CPU address and read the desired location onto the RAM data output pin. The 8202 also generates an XACK strobe which is used to latch the RAM data for the CPU, as shown in Figure 2. (See "READY HANDSHAKE SIGNALS" for further uses of XACK.)

We can determine the amount of time it takes to generate valid READ data by calculating the delay from  $\overline{RD}\downarrow$  to  $\overline{CAS}\downarrow$ , and add this with the RAM's CAS access time (t<sub>CAC</sub>) and the latch's propagation delay. In other words,

states are required. WAIT states can be used to extend In a distributed refresh system the memory controller

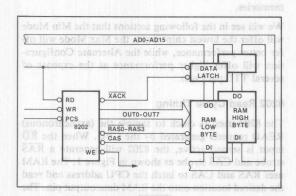

Figure 2. Basic Memory Architecture latch the RAM data for the CPU, as shown in Figure 2.

Since the t<sub>CC</sub> parameter is a function of the 8202's operating frequency, we can minimize tRI DV by running the 8202 at the highest possible frequency. We can also reduce tRLDV by choosing a RAM with a faster CAS access time. Table 1 shows the minimum tripy for the various RAMs, based on the maximum 8202 frequency for that RAM. If system constraints force you to choose a slower 8202 operating frequency, then your tRLDV will increase, which may slow down your CPU.

Table 1. 8202 System Timing

RAM TYPE	trac	tcac	tRLDV1	tca1	t <sub>RLXA</sub> 1	tcc, MIN <sup>1,2</sup>	fMAX

## Read Access Time (Min Mode)

In order to operate with no WAIT states, our memory system shown in Figure 3 must guarantee valid READ time systems allow a processor to enter a limit within:

$$t_{RLDV} \le 2 t_{CLCL} (CPU) - t_{CLRL, MIN} (CPU)$$
 $-t_{DVCL, MIN} (CPU)$ 

Table 2 lists these times for various CPUs, operating at 5 MHz and 8 MHz. If your system has any additional buffers for the RD, WR, or data lines, you must subtract their propagation delay from the tRLDV values in Table 1 to derive your system access requirements.

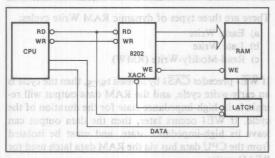

Figure 3. Unbuffered Min Mode Configuration

Now we merely have to compare our system requirements from Table 2 with the memory access times in Table 1 to see if our RAM speed selection and 8202 operating frequency will work in our system with no WAIT states. If our system requirement is too fast for our first choice memory configuration, we will have to choose either a faster RAM, or add WAIT states.

If you choose to run with WAIT states, you can multiply the CPU clock period by the number of WAIT states, and add this number to the t<sub>RLDV</sub> values in Table 2 to derive your new CPU access requirements. For example, a 5 MHz 8086 Min Mode configuration with no WAIT states requires a read access time of 205 nanoseconds, while the same configuration would need an access time of only 405 nanoseconds if we operate with one WAIT state. If we examine Table 1, we see that there is no RAM configuration which can run without WAIT states in a 5 MHz 8086 configuration; but we can use any 2118 speed selection if we operate with one WAIT state.

Table 2. Read Cycle Access Requirements

		MIN MODE			MAX	MODE	
	8086-2	8086	8088	8086-2	8086	8088	8089
fcpu	8 MHz	5 MHz	5 MHz	8 MHz	5 MHz	5 MHz	5 MHz
tRLDV	130	205	205	195	335	335	335
tRLDV,	209	345	345	209	345	345	415

# Read Access Time (Max Mode)

Figure 4 illustrates the standard unbuffered Max Mode configuration. In order to run with no WAIT states, we need to guarantee a READ access time of

$$t_{RLDV} = 2 t_{CLCL} (CPU) - t_{CLML, MAX} (8288)$$
  
-  $t_{DVCL, MIN} (CPU)$ 

These times are listed in Table 2 for the various CPUs, operating at 5 MHz and 8 MHz. If your system has buffers on the RD, WR, or data lines, you must subtract their propagation delay from the t<sub>RLDV</sub> values in Table 2.

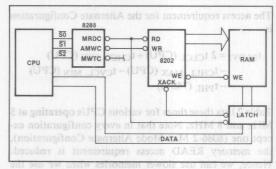

Figure 4. Unbuffered Max Mode Configuration

If we compare the Max Mode  $t_{RLDV}$  requirements in Table 2 with the Min Mode requirements, we notice that the Max Mode can run with a memory configuration that is 130 nsec slower than the memory required for an equivalent Min Mode configuration! In fact, all 5 MHz Max Mode CPU configurations can operate with no WAIT states in any of the 2118 memory configurations. Even the 8 MHz 8086-2 configuration can operate with all but one RAM configuration (2117-4) with only one WAIT state. This illustrates the advantage of using the Max Mode and the 8288 to generate the  $\overline{\rm RD}$  signal for the 8202 when compared with the lower chip count Min Mode.

# **READ Access Time (Alternate Configuration)**

We can reduce our memory speed requirement even further by using the Alternate Configuration shown in Figure 5. This circuit uses the CPU status information to generate 8202  $\overline{RD}$  and  $\overline{WR}$  commands which start earlier in the memory cycle than either the Min Mode or the Max Mode. As previously stated, the Alternate Configuration can be used when the CPU is strapped in either the Min Mode or the Max Mode.

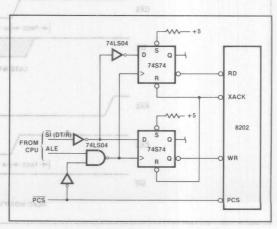

Figure 5. Alternate Configuration

The access requirement for the Alternate Configuration

 $t_{RLDV1} = 2 t_{CLCL} (CPU) + t_{CHCL, MIN} (CPU)$ -t<sub>CHLL</sub>, MAX (CPU) -t<sub>CVCL</sub>, MIN (CPU) - tphi (74S74)

Table 2 lists these times for various CPUs operating at 5 MHz and 8 MHz. Note that in every configuration except one (8086-2 Max Mode Alternate Configuration), the memory READ access requirement is reduced. Hence, we can use slower memories when we use the Alternate Configuration in all but this one configuration. In general, the Alternate Configuration offers a significant advantage over the standard Min Mode, but little advantage over the standard Max Mode for READ cycles. The women a drive air men should sald sald

# 8202 Write Cycle Timing Theo about and instavingo

8202 WRITE cycles have timing similar to READ cycles, except the WE line is pulsed for the WRITE cycle; all other signal times are the same as a READ cycle.

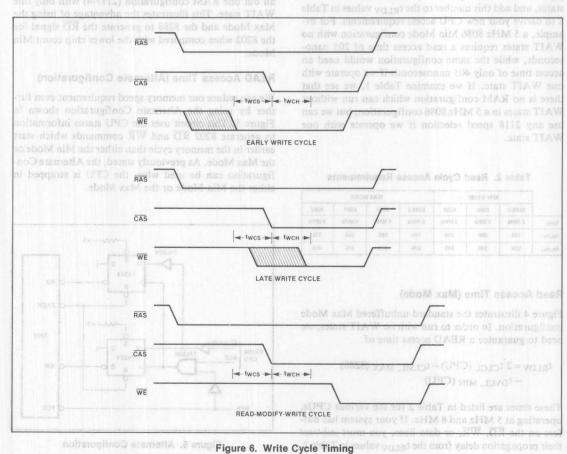

There are three types of dynamic RAM Write cycles:

- a) Early Write
- b) Late Write
- c) Read-Modify-Write (RMW)

If WE↓ precedes CAS↓ by at least twcs, then the cycle is an early-write cycle, and the RAM data output will remain in its high-impedance state for the duration of the cycle. If WE↓ occurs later, then the data output can leave its high-impedance state, and must be isolated from the CPU data bus via the RAM data latch used for READ cycles.

The dynamic RAM uses the WE and CAS signals to strobe the WRITE data into the RAM. If WE↓ precedes CAS, as shown in Figure 6, then the data setup and hold times are measured relative to CAS, and the cycle is called an "early-WRITE" cycle. If the CPU starts a WRITE cycle by driving WR active, and does not let WR go inactive until CAS1, then the 8202 will always perform an early-WRITE cycle.

The following three sections will illustrate 8202 WRITE cycles for Min Mode, Max Mode, and Alternate Con-

figurations. In most cases, we will use the 8202 early-WRITE configuration. However, in some cases, we will use a late-WRITE or READ-modify-WRITE 8202 configuration to prevent the RAM from storing the wrong information from the CPU's multiplexed address/data bus. In each case, we will examine the early-WRITE configuration first to see if the WRITE cycle will have adequate data setup and hold time for the RAM.

The twldv data setup times for the various CPU configurations are listed in Table 3. In order to use the early-WRITE configuration of the 8202, we must guarantee:

$$t_{WLDV, MIN}$$
 (CPU) +  $t_{CC, MIN}$  (8202) =  $t_{DS, MIN}$  (RAM) (Equation 1)

If this condition is not met by our system, we will have to either

- 1) Delay the 8202 WR signal, which will cause CAS ↓ to occur later in the bus cycle; or
- 2) Disconnect the 8202 WE signal from the RAM, and generate a delayed WE, that goes active after the WRITE data becomes valid, but not so late in the cycle that the RAM's t<sub>CWL</sub> parameter is violated.

The first alternative can be accomplished using the circuits shown in Figure 7. Both of these circuits will increase the  $t_{WLDV}$ , MIN values listed in Table 3 by an amount of time based on the CPU clock.

Figure 8 illustrates a method of generating a delayed WE for the RAM using the 8288 MWTC signal, while starting the WRITE cycle with the 8288 AMWC signal. This circuit has the advantage of allowing the 8202 to respond with SACK\$\(\psi\$ early enough to prevent any WAIT states in certain configurations. For this reason, the second alternative (Figure 8) is more favorable over the first configuration.

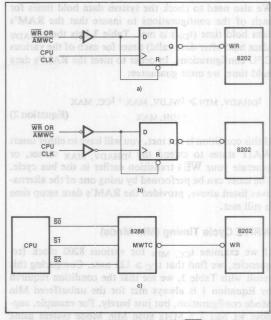

Figure 7. Generating a Delayed WR for 8202

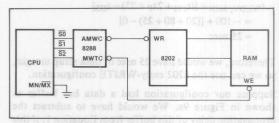

Figure 8. Using AMWC and MWTC for WRITE Cycles

tDHADV	420	Ty W	420	nan e	420		420		420		

1 ASSUMES AMWC USED. ADD tolol IF MWTC USED.

We also need to check the system data hold times for each of the configurations to insure that the RAM's data hold time ( $t_{DH}$ ) is met. Table 3 lists the  $t_{DHADV}$  (data hold after data valid) times for each of the various CPU configurations. In order to meet the RAM's data hold time, we must guarantee:

$$t_{DHADV, MIN} \ge t_{WLDV, MAX} + t_{CC, MAX} + t_{DH, MAX}$$
 (Equation 2)

If this condition is not met, you will have to either insert WAIT states to extend the t<sub>DHADV</sub>, <sub>MAX</sub> values, or generate your WE \( \psi\) transition earlier in the bus cycle. The latter can be performed by using one of the alternatives listed above, provided the RAM's data setup time is still met.

## WRITE Cycle Timing (Min Mode)

If we examine  $t_{\rm CC}$ ,  $_{\rm MIN}$  for various 8202 clock frequencies, we find that  $t_{\rm CC} \geqslant 125$  nsec. Comparing this result with Table 3, we see that the condition required by Equation 1 is always met for the unbuffered Min Mode configuration, but just barely. For example, suppose we had a 5 MHz 8086 Min Mode system using 2118-3's ( $t_{\rm DS} = 0$  nsec) with a 25 MHz 8202; Equation 1 becomes:

$$t_{WLDV, MIN} + [(t_{PH} + 2t_P + 25) - t_{DS}]$$
  
= -100 + [(20 + 80 + 25) - 0]  
= 25 nsec

Therefore, we would have 25 nsec of data setup margin, so we can use the 8202 early-WRITE configuration.

Suppose our configuration had a data bus buffer as shown in Figure 9a. We would have to subtract the propagation delay of this buffer from Equation 1; if this delay is greater than 25 nanoseconds, then we cannot use the 8202 early-WRITE configuration.

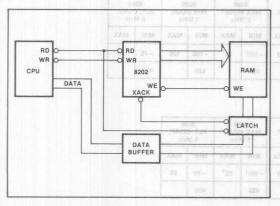

Figure 9a. Buffered Min Mode Configuration

Next, we need to examine our system to insure the RAM's data hold time is met. For the same system configuration, we can solve Equation 2:

$$t_{DHADV, MIN} \ge t_{WLDV, MAX} + t_{CC, MAX} + t_{DH}$$
  
= 100 + (t<sub>PH</sub> + 3 t<sub>P</sub> + 85) + 25  
= 350 nsec

Examining Table 3, we see that Equation 2 is satisfied with 70 nsec of margin. If we added any data buffers to our system, this margin would *increase*; if we buffer the  $8202 \overline{WR}$  input, this margin will decrease.

## Write Cycle Timing (Max Mode)

Let's see if we can get an 8 MHz 8086-2 Max Mode system to operate with 2118-4's in a 25 MHz 8202 early-WRITE configuration as shown in Figure 9b. Solving equation 1, we find:

$$t_{\text{WLDV}} + [(t_{\text{PH}} + 2t_{\text{P}} + 25) - t_{\text{DS}}] - t_{\text{IVOV}} (8286)$$

$$= -50 + [(20 + 80 + 25) - 0] - 35$$

$$= 40 \text{ nsec}$$

so we see we can use the early-WRITE configuration. Had we chosen a 5 MHz 8086 Max Mode configuration, we see from Table 3 that t<sub>WLDV</sub> would decrease by 50 nanoseconds, which means we would not have adequate data set-up time.

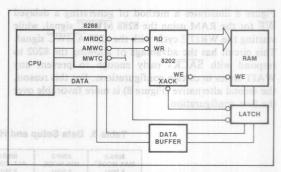

Figure 9b. Buffered Max Mode Configuration

## Write Cycle Timing (Alternate Configuration)

In general, the Alternate Configuration offers little advantage over the standard Min Mode or Max Mode, except in the earlier generation of the READY acknowledge signals, SACK and XACK. In some cases, using the Alternate Configuration will force you to generate a delayed WE signal, since the 8202 WR signal goes active earlier in the bus cycle for the Alternate Configuration than it does for either the Min Mode or the Max Mode. So, unless you need to speed up your READY signal to reduce unnecessary WAIT states for WRITE cycles, the Alternate Configuration for WRITE cycles may not offer any performance advantage for your system.

## Handling 8-Bit Write Cycles in 16-Bit Systems

Systems which perform 8-bit WRITE cycles in a 16-bit memory array require a slight modification of the WE control described previously. The memory must be broken into two 8-bit arrays with separate WE control, as shown in Figure 10.

CPU signals A0 and BHEN determine the type of bus cycle to be performed. If A0=0, then the even byte is transferred on AD0-7; if BHEN is active, then the odd byte is transferred on AD8-AD15. A word transfer is performed when A0 = 0 and  $\overline{BHEN}$  is active.

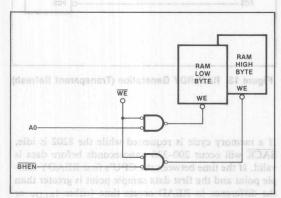

Figure 10. 8/16-Bit Write Cycle Control

# be used to generate the CPU's REA

Multibus Byte Swap ADAC to mot beyelsb s ,ear To permit compatibility with existing 8-bit CPU boards, the Multibus specification requires all byte transfers to occur on the 8 least significant data lines (DATO-DAT7). Figure 11 illustrates how to handle 8-bit and 16-bit bus cycles in a Multibus environment.

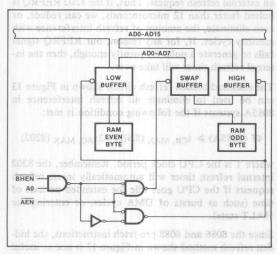

Figure 11. Multibus Byte Swap

Although Multibus uses the signals BHEN and A0, their meaning is slightly different than the CPU pin definitions. If BHEN is inactive, then the bus cycle is always 8 bits, and always uses DAT0-DAT7; if BHEN is active, then the cycle is always 16-bits, and A0 = 0.

The High Byte Buffer and the Low Byte Buffer are enabled for all word transfers, and for all byte transfers to an even address. The Swap Byte Buffer is enabled only for byte transfers to an odd address.

This control logic will allow a 16-bit memory board to be compatible with both 8-bit CPU boards and 16-bit CPU boards.

## **PCS** Generation

In order to start a memory cycle, the 8202 requires its PCS input, as well as RD or WR, to be active. Once a memory cycle is started, the 8202 will complete it, even if PCS goes inactive. This feature can be used for battery-backup RAM designs. If you have a battery backed up design, RD, WR and PCS should be pulled up to the battery supply.

Normal decoding of the processor address bus can be used to generate PCS. Since combinational logic (or even a bipolar PROM) is typically used to generate PCS; you must examine your system timing to make sure PCS is stable before RD or WR goes active. If your decoding time is greater than the address set-up to command time, then two things can happen:

- 1) Your memory cycle will not start until PCS goes active.
- 2) You may cause the 8202 to start an unwanted cycle due to a decoder glitch.

Remember, your decoding time is the amount of time it takes to ensure that only one device is selected, and that all other devices are deselected. Your decoder outputs may change after an address transition, and will only be stable after the decoding time has expired.

# Ready Handshake Signals (SACK and XACK)

If our dynamic memory system was always available when the CPU requested a memory cycle, then we could generate our RAMRDY signal as shown in Figure 13; if our RAM required no WAIT states, we could tie the READY line high, assuming the I/O and the rest of the memory (e.g., PROM) did not need any WAIT states.

In systems which use asynchronous refresh, we cannot use these methods of READY generation, since extra WAIT states are needed when a memory cycle is requested while refresh is in progress. This CPU holdoff can be performed using the 8202 XACK and SACK signals. the time they sample data, XACE

XACK is a Multibus compatible acknowledge handshake signal, since it only goes active after READ data is valid, and after WRITE data has been latched. XACK

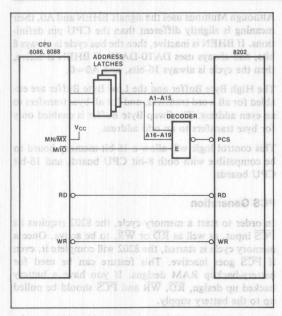

Figure 12a. 8202 PCS Generation — Minimum Mode

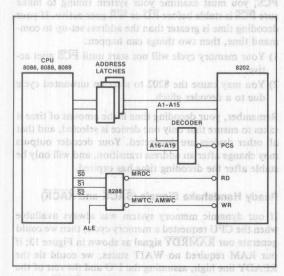

Figure 12b. 8202 PCS Generation - Maximum Mode

can be connected to the CPU's Ready input through an inverter.

Since most CPUs sample READY 1-2 clocks ahead of the time they sample data, XACK may cause more WAIT states than you really need; if your system has sufficient time between the READY sample and the data sample, SACK can be used.

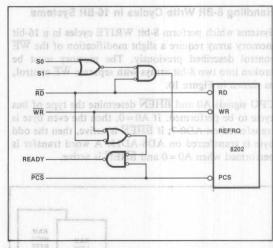

Figure 13. RAM RDY Generation (Transparent Refresh)

If a memory cycle is requested while the 8202 is idle, \$\overline{SACK}\$ will occur 200-320 nanoseconds before data is valid. If the time between the CPU's first READY sample point and the first data sample point is greater than the difference in READ access time (either t\_{RLDV}) or t\_{RLDV1}, depending on your configuration) and the t\_{CA}, \$\overline{MAX}\$ time for your 8202 configuration, then \$\overline{SACK}\$ can be used to generate the CPU's READY signal. Otherwise, a delayed form of \$\overline{SACK}\$ (or \$\overline{XACK}\$) should be used to generate the READY signal.

## Refresh Considerations lines that I will no make

The 8202 has an internal timer which generates refresh requests every 12–16 microseconds, unless it is reset by an external refresh request. Thus, if the 8202 REFRQ is pulsed faster than 12 microseconds, we can reduce, or even eliminate, the amount of refresh interference with memory cycles. If, for any reason, our REFRQ signal fails to generate a pulse frequently enough, then the internal refresh timer will take over.

The standard hidden refresh circuit shown in Figure 13 can be used to eliminate all refresh interference in 8085A systems if the following condition is met:

$$4T (8085A) \ge t_{CR, MAX} (8202) + 2t_{RC, MAX} (8202)$$

where T is the CPU clock period. Remember, the 8202 internal refresh timer will automatically insert refresh requests if the CPU goes idle for extended periods of time (such as bursts of DMA cycles, or entering the HALT state).

Since the 8086 and 8088 pre-fetch instructions, the hidden refresh method shown in Figure 13 is not as useful as it is for 8085A systems. The 8086 Family CPUs will

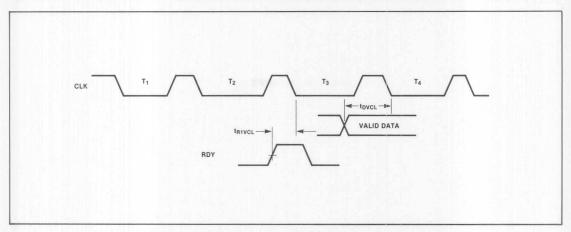

Figure 14. 8086 Family Data and READY Sample Points

have to use the 8202 internal refresh, and suffer the 3-7% performance degradation due to refresh interference. In reality, the performance degradation will be even less, since the instruction queue is normally full, and there is less chance of refresh interference than in an 8085A system.

### Finally, the drive provides NOITOUDONTNI 11

Most microcomputer systems in use today require lowcost, high-density removable magnetic media for information storage. In the area of removable media, a designer's choice is limited to magnetic tapes and floppy disks (flexible diskettes), both of which offer non-volatile data storage. The choice between these two technologies is relatively straight-forward for a given application. Since disk drives are designed to permit random access to stored information, they are significantly faster than tape units. For example, locating information on a disk requires less than a second, while tape movement (even at the fastest rewind or fast-forward speed) often requires several minutes. This random access ability permits the use of floppy disks in on-line storage applications (where information must be located, read, and modified/updated in real-time under program or operator control). Tapes, on the other hand, are ideally suited to archival or back-up storage due to their large storage capacities (more than 10 million bytes of data can be archived on a cartridge tape).

A sophisticated controller is required to capitalize on the abilities of the disk storage unit. In the past, disk controller designs have required upwards of 150 ICs. Today, the single-chip 8272 Floppy Disk Controller (FDC) plus approximately 30 support devices can handle up to four million bytes of on-line data storage on four floppy disk drives.

### The Floppy Disk

A floppy disk is a circular piece of thin plastic material covered with a magnetic coating and enclosed in a protective jacket (Figure 1). The circular piece of plastic revolves at a fixed speed (approximately 360 rpm) within its jacket in much the same manner that a record revolves at a fixed speed on a stereo turntable. Disks are manufactured in a variety of configurations for various storage capacities. Two standard physical disk sizes are commonly used. The 8-inch disk (8 inches square) is the larger of the two sizes; the smaller size (5-1/4 inches square) is often referred to as a mini-floppy. Singlesided disks can record information on only one side of the disk, while double-sided disks increase the storage capacity by recording on both sides. In addition, disks are classified as single-density or double-density. Doubledensity disks use a modified recording method to store twice as much information in the same disk area as can be stored on a single-density disk. Table 1 lists storage capacities for standard floppy disk media.

A magnetic head assembly (in contact with the disk) writes information onto the disk surface and subsequently reads the data back. This head assembly can move from the outside edge of the disk toward the center in fixed increments. Once the head assembly is

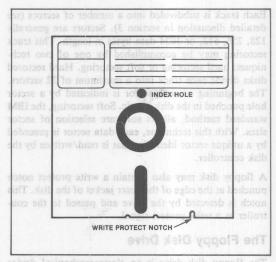

Figure 1. A Floppy Diskette

positioned at one of these fixed positions, the head can read or write information in a circular path as the disk revolves beneath the head assembly. This method divides the surface into a fixed number of cylinders (as shown in Figure 2). There are normally 77 cylinders on a standard disk. Once the head assembly is positioned at a given cylinder, data may be read or written on either side of the disk. The appropriate side of the disk is selected by the read/write head address (zero or one). Of course, a single-sided disk can only use head zero. The combination of cylinder address and head address uniquely specifies a single circular track on the disk. The physical beginning of a track is located by means of a small hole (physical index mark) punched through the plastic near the center of the disk. This hole is optically sensed by the drive on every revolution of the disk.

Table 1. Formatted Disk Capacities

Single-Density Format	same interl a immer c			
	0 9/1 128			-
Sectors/Track	9192 11926	vino 15	dans a8	evisto e4
Tracks/Disk	ideo ad77	o siam 77	ouno 77	, bete77
Bytes/Disk	256,256	295,680	315,392	315,392
Double-Density Format				
Bytes/Sector	128	256	512	1024
Sectors/Track	52	30	16	8
Tracks/Disk	77	77	77	77
Bytes/Disk	512,512	591,360	630,784	630,784

Each track is subdivided into a number of sectors (see detailed discussion in section 3). Sectors are generally 128, 256, 512, or 1024 data bytes in length. This track sectoring may be accomplished by one of two techniques: hard sectoring or soft sectoring. Hard sectored disks divide each track into a maximum of 32 sectors. The beginning of each sector is indicated by a sector hole punched in the disk plastic. Soft sectoring, the IBM standard method, allows software selection of sector sizes. With this technique, each data sector is preceded by a unique sector identifier that is read/written by the disk controller.

A floppy disk may also contain a write protect notch punched at the edge of the outer jacket of the disk. This notch is detected by the drive and passed to the controller as a write protect signal.

### The Floppy Disk Drive

The floppy disk drive is an electromechanical device that records data on, or reads data from, the surface of a floppy disk. The disk drive contains head control electronics that move the head assembly one increment (step) forward (toward the center of the disk) or backward (toward the edge of the disk). Since the recording head must be in contact with the disk material in order to read or write information, the disk drive also contains head-load electronics. Normally the read/write head is unloaded until it is necessary to read or write information on the floppy disk. Once the head assembly has been positioned over the correct track on the disk, the head is loaded (brought into contact with the disk). This sequence prevents excessive disk wear. A small time penalty is paid when the head is loaded. Approximately thirty to fifty milliseconds are needed before data may be reliably read from, or written to, the disk. This time is known as the head load time. If desired, the head may be moved from cylinder to cylinder while loaded. In this manner, only a small time interval (head settling time) is required before data may be read from the new cylinder. The head settling time is often shorter than the head load time. Typically, disk drives also contain drive select logic that allows more than one physical drive to be connected to the same interface cable (from the controller). By means of a jumper on the drive, the drive number may be selected by the OEM or end user. The drive is enabled only when selected; when not selected, all control signals on the cable are ignored.

315,392	315,392	295,680		
				Double-Density Format
1024 8 77	512 16 77	256 30 77	128 52 77	Bytes/Sector Sectors/Track Tracks/Disk
630,784	630,784			Bytes/Disk

Finally, the drive provides additional signals to the system controller regarding the status of the drive and disk. These signals include:

Drive Ready — Signals the system that the drive door as is closed and that a floppy disk is inserted into the drive.

Track Zero — Indicates that the head assembly is located over the outermost track of the disk.

This signal may be used for calibration of the disk drive at system initialization and after an error condition.

Write Protect — Indicates that the floppy disk loaded into the drive is write protected.

Dual Sided — Indicates that the floppy disk in the drive is dual-sided.

Write Fault — Indicates that an error occurred during a recording operation.

Index — Informs the system that the physical index mark of the floppy disk (signifying the start of a data track) has been sensed.

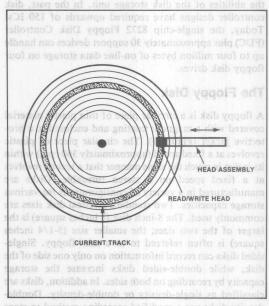

Figure 2. Concentric Cylinders on a Floppy Diskette

A magnetic head assembly (in contact with the disk) writes information onto the disk surface and subsequently reads the data back. This head assembly can nove from the outside edge of the disk toward the beater in fixed increments. Once the head assembly is

### 4. OUDOTOTEN UVERVIEW 32500A VIOLEN

A disk subsystem consists of the following functional electronic units:

- 1. Disk Controller Electronics (188 desuper a sellottino)
- 2. Disk Drive Electronics
- Controller/Disk Interface (cables, drivers, terminators)
- 4. Controller/Microprocessor System Interface

The operation of these functional units is discussed in the following paragraphs.

### Controller Electronics begins been of relient

The disk controller is responsible for converting highlevel disk commands (normally issued by software executing on the system processor) into disk drive commands. This function includes:

- 1. Disk Drive Selection Disk controllers typically manage the operations of multiple floppy disk drives. This controller function permits the system processor to specify which drive is to be used in a particular operation.
- Track Selection The controller issues a timed sequence of step pulses to move the head from its current location to the proper disk cylinder from which data is to be read or to which data is to be written. The controller stores the current cylinder number and computes the stepping distance from the current cylinder to the specified cylinder. The controller also manages the head select signal to select the correct side of the floppy disk.
- 3. Sector Selection The controller monitors the data on a track until the requested sector is sensed.
- 4. Head Loading The disk controller determines the times at which the head assembly is to be brought in contact with the disk surface in order to read or write data. The controller is also responsible for waiting until the head has settled before reading or writing information. Often the controller maintains the head loaded condition for up to 16 disk revolutions (approximately 2 seconds) after a read or write operation has been completed. This feature eliminates the head load time during periods of heavy disk I/O activity.
- 5. Data Separation The actual signal recorded on a floppy disk is a combination of timing information (clock) and data. The serial READ DATA input (from the disk drive) must be converted into two signal streams: clock and data. (The READ DATA input operates at 250K bits/second for single-density disks and 500K bits/second for double-density

- disks.) The serial data must also be assembled into 8-bit bytes for transfer to system memory. A byte must be assembled and transferred every 32 microseconds for single-density disks and every 16 microseconds for double-density.
- 6. Error Checking Information recorded on a floppy disk is subject to both hard and soft errors. Hard (permanent) errors are caused by media defects. Soft errors, on the other hand, are temporary errors caused by electromagnetic noise or mechanical interference. Disk controllers use a standard error checking technique known as a Cyclic Redundancy Check (CRC). As data is written to a disk, a 16-bit CRC Character is computed and also stored on the disk. When the data is subsequently read, the CRC character allows the controller to detect data errors. Typically, when CRC errors are detected, the controlling software retries the failed operation (attempting to recover from a soft error). If data cannot reliably be read or written after a number of retries, the system software normally reports the error to the operator. Multiple CRC errors normally indicate unrecoverable media error on the current disk track. Subsequent recovery attempts must be defined by the system designers and tailored to meet system interfacing requirements.

Today, single-chip digital LSI floppy disk controllers such as the 8272 perform all the above functions with the exception of data separation. A data separation circuit (a combination of digital and analog electronics) synchronizes itself to the actual data rate of the disk drive. This data rate varies from drive to drive (due to mechanical factors such as motor tolerances) and varies from disk to disk (due to temperature effects). In order to operate reliably with both single- and double-density storage, the data separation circuit must be based on phase-locked loop (PLL) technology. The phase-locked loop data separation logic is described in section 5. The separation logic, after synchronizing with the data stream, supplies a data window to the LSI disk controller. This window differentiates data information from clock information within the serial stream. The controller uses this window to reconstruct the data previously recorded on the floppy disk.

# Drive Electronics (Section 2) and stable about 1026

Each floppy disk drive contains digital electronic circuits that translate TTL-compatible command signals into electromechanical operations (such as drive selection and head movement/loading) and that sense and report disk or drive status to the controller (e.g., drive ready, write fault, and write protect). In addition, the drive electronics contain analog components to sense, amplify, and shape data pulses read from, or written to, the floppy disk surface by the read/write head.

### Controller/Drive Interface

The controller/drive interface consists of high-current line drivers, Schmitt triggered input gates, and flat or twisted pair cable(s) to connect the disk drive electronics to the controller electronics. Each interface signal line is resistively terminated at the end of the cable farthest from the line drivers. Eight-inch drives may be directly interfaced by means of 50-conductor flat cable. Generally, cable lengths should be less than ten feet in order to maintain noise immunity.

Normally, provisions are made for up to four disk drives to share the same interface cable. The controller may operate as many cable assemblies as practical. LSI floppy disk controllers typically operate one to four drives on a single cable.

### Processor/Memory Interface interface interface

The disk controller must interface to the system processor and memory for two distinct purposes. First, the processor must specify disk control and command parameters to the controller. These parameters include the selection of the recording density and specification of disk formatting information (discussed in section 3). In addition to disk parameter specification, the processor must also send commands (e.g., read, write, seek, and scan) to the controller. These commands require the specification of the command code, drive number, cylinder address, sector address, and head address. Most LSI controllers receive commands and parameters by means of processor I/O instructions.

In addition to this I/O interface, the controller must also be designed for high-speed data transfer between memory and the disk drive. Two implementation methods may be used to coordinate this data transfer. The lowest-cost method requires direct processor intervention in the transfer. With this method, the controller issues an interrupt to the processor for each data transfer. (An equivalent method allows the processor to poll an interrupt flag in the controller status word.) In the case of a disk write operation, the processor writes a data byte (to be encoded into the serial output stream) to the disk controller following the receipt of each controller interrupt. During a disk read operation, the processor reads a data byte (previously assembled from the input data stream) from the controller after each interrupt. The processor must transfer a data byte from the controller to memory or transfer a data byte from memory to the disk controller within 16 or 32 microseconds after each interrupt (double-density and single-density response times, respectively).

If the system processor must service a variety of other interrupt sources, this interrupt method may not be practical, especially in double-density systems. In this case, the disk controller may be interfaced to a Direct Memory Access (DMA) controller. When the disk controller requires the transfer of a data byte, it simply activates the DMA request line. The DMA controller interfaces to the processor and, in response to the disk controller's request, gains control of the memory interface for a short period of time—long enough to transfer the requested data byte to/from memory. See section 6 for a detailed DMA interface description.

### 3. DISK FORMAT TORRODO TO THE TORRODO A

New floppy disks must be written with a fixed format by the controller before these disks may be used to store data. Formatting is a method of taking raw media and adding the necessary information to permit the controller to read and write data without error. All formatting is performed by the disk controller on a track-bytrack basis under the direction of the system processor. Generally, a track may be formatted at any time. However, since formatting "initializes" a complete disk track, all previously written data is lost (after a format operation). A format operation is normally used only when initializing new floppy disks. Since soft-sectoring in such a predominant formatting technique (due to IBM's influence), the following discussion will limit itself to soft-sectored formats.

# Data Recording Techniques

Two standard data recording techniques are used to combine clock and data information for storage on a floppy disk. The single-density technique is referred to as FM encoding. In FM encoding (see Figure 3), a double frequency encoding technique is used that inserts a data bit between two adjacent clock bits. (The presence of a data bit represents a binary "one" while the absence of a data bit represents a binary "zero.") The two adjacent clock bits are referred to as a bit cell, and except for unique field identifiers, all clock bits written on the disk are binary "ones." In FM encoding, each data bit is written at the center of the bit cell and the clock bits are written at the leading edge of the bit cell.

The encoding used for double-density recording is termed MFM encoding (for "Modified FM"). In MFM encoding (Figure 3) the data bits are again written at the center of the bit cell. However, a clock bit is written at the leading edge of the bit cell only if no data bit was written in the previous bit cell and no data bit will be written in the present bit cell.

# Sectors in minut to notispidmon a 21 Asib vogoli

Soft-sectored floppy disks divide each track into a number of data sectors. Typically, sector sizes of 128, 256, 512, or 1024 data bytes are permitted. The sector size is specified when the track is initially formatted by the controller. Table 1 lists the single- and double-

2-136 AFN 01795A

density data storage capacities for each of the four sector sizes. Each sector within a track is composed of the following four fields (illustrated in Figure 4):

- 1. Sector ID Field This field, consisting of seven bytes, is written only when the track is formatted. The ID field provides the sector identification that is used by the controller when a sector must be read or written. The first byte of the field is the ID address mark, a unique coding that specifies the beginning of the ID field. The second, third, and fourth bytes are the cylinder, head, and sector addresses, respectively, and the fifth byte is the sector length code. The last two bytes are the 16-bit CRC character for the ID field. During formatting, the controller supplies the address mark. The cylinder, head, and sector addresses and the sector length code are supplied to the controller by the processor software. The CRC character is derived by the controller from the data in the first five bytes.
- 2. Post ID Field Gap The post ID field gap (gap 2) is written initially when the track is formatted. During subsequent write operations, the drive's write circuitry is enabled within the gap and the trailing bytes of the gap are rewritten each time the sector is updated (written). During subsequent read operations, the trailing bytes of the gap are used to synchronize the data separator logic with the upcoming data field.
- Data Field The length (number of data bytes) of the data field is determined by software when the track is formatted. The first byte of the data field is the data address mark, a unique coding that specifies

- the beginning of the data field. When a sector is to be deleted, (e.g., a hard error on the disk), a deleted data address mark is written in place of the data address mark. The last two bytes of the data field comprise the CRC character.
- 4. Post Data Field Gap The post data field gap (gap 3) is written when the track is formatted and separates the preceding data field from the next physical ID field on the track. Note that a post data field gap is not written following the last physical sector on a track. The gap itself contains a programselectable number of bytes. Following a sector update (write) operation, the drive's write logic is disabled during the gap. The actual size of gap 3 is determined by the maximum number of data bits that can be recorded on a track, the number of sectors per track and the total sector size (data plus overhead information). The gap size must be adjusted so that it is large enough to contain the discontinuity generated on the floppy disk when the write current is turned on or off (at the start or completion of a disk write operation) and to contain a synchronization field for the upcoming ID field (of the next sector). On the other hand, the gaps must be small enough so that the total number of data bits required on the track (sectors plus gaps) is less than the maximum number of data bits that can be recorded on the track. The gap size must be specified for all read, write, and format operations. The gap size used during disk reads and writes must be smaller than the size used to format the disk to avoid the splice points between contiguous physical sectors. Suggested gap sizes are listed in Table 9.

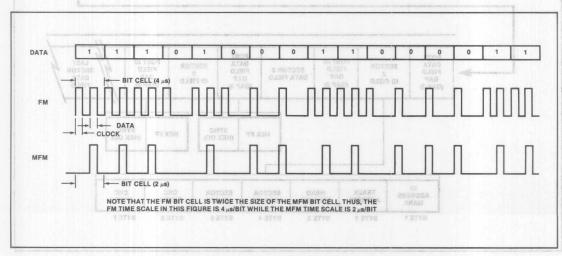

Figure 4. Standard Igniboard MFM Encoding Sac 204 Manuall

### Tracks stock a mod W , blait stab and to guinariged add

The overall format for a track is illustrated in Figure 4. Each track consists of the following fields:

- 1. Pre-Index Gap The pre-index gap (gap 5) is written only when the track is formatted.
- Index Address Mark The index address mark consists of a unique code that indicates the beginning of a data track. One index mark is written on each track when the track is formatted.
- Post Index Gap The post index gap (gap 1) is used during disk read and write operations to syn-

- chronize the data separator logic with the data to be read from the ID field (of the first sector). The post index gap is written only when the disk is formatted.
- 4. Sectors The sector information (discussed above) is repeated once for each sector on the track.
- 5. Final Gap The final gap (gap 4) is written when the track is formatted and extends from the last physical data field on the track to the physical index mark. The length of this gap is dependent on the number of bytes per sector specified, the lengths of the program-selectable gaps specified, and the drive speed.

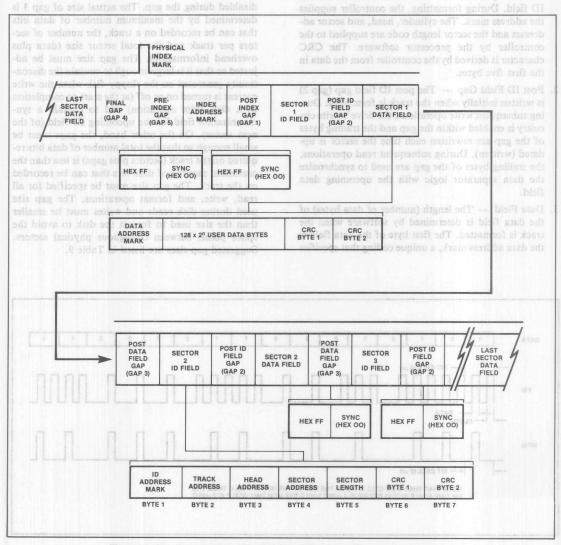

Figure 4. Standard Floppy Diskette Track Format (From SBC 204 Manual)

2-138

### Sector Interleaving AT ARZAHS MOTTUDEXE

The initial formatting of a floppy disk determines where sectors are located within a track. It is not necessary to allocate sectors sequentially around the track (i.e., 1,2,3,...,26). In fact, is is often advantageous to place the sectors on the track in a non-sequential order. Sequential sector ordering optimizes sector access times during multi-sector transfers (e.g., when a program is loaded) by permitting the number of sectors specified (up to an entire track) to be transferred within a single revolution of the disk. A technique known as sector interleaving optimizes access times when, although sectors are accessed sequentially, a small amount of processing must be performed between sector reads/writes. For example, an editing program performing a text search reads sectors sequentially, and after each sector is read, performs a software search. If a match is not found, the software issues a read request for the next sector. Since the floppy disk continues to rotate during the time that the software executes, the next physical sector is already passing under the read/write head when the read request is issued, and the processor must wait for another complete revolution of the disk (approximately 166 milliseconds) before the data may actually be input. With interleaving, the sectors are not stored sequentially on a track; rather, each sector is physically removed from the previous sector by some number (known as the interleave factor) of physical sectors as shown in Figure 5. This method of sector allocation provides the processor additional execution time between sectors on the disk. For example, with a 26 sector/track format, an interleave factor of 2 provides 6.4 milliseconds of processing time between sequential 128 byte sector accesses.

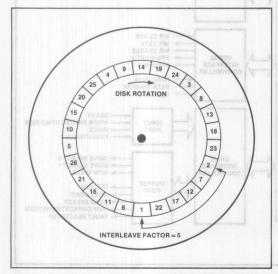

Figure 5. Interleaved Sector Allocation Within a Track Read Deleted Data

To calculate the correct interleave factor, the maximum processor time between sector operations must be divided by the time required for a complete sector to pass under the disk read/write head. After determining the interleave factor, the correct sector numbers are passed to the disk controller (in the exact order that they are to physically appear on the track) during the execution of a format operation.

# 4. THE 8272 FLEXIBLE DISKETTE CONTROLLER

The 8272 is a single-chip LSI Floppy Disk Controller (FDC) that contains the circuitry necessary to implement both single-and double-density floppy disk storage subsystems (with up to four dual-sided disk drives per FDC). The 8272 supports the IBM 3740 single-density recording format (FM) and the IBM System 34 doubledensity recording format (MFM). With the 8272, less than 30 ICs are needed to implement a complete disk subsystem. The 8272 accepts and executes high-level disk commands such as format track, seek, read sector, write sector, and read track. All data synchronization and error checking is automatically performed by the FDC to ensure reliable data storage and subsequent retrieval. External logic is required only for the generation of the FDC master clock and write clock (see Section 6) and for data separation (Section 5). The FDC provides signals that control the startup and base frequency selection of the data separator. These signals greatly ease the design of a phase-locked loop data separator.

In addition to the data separator interface signals, the 8272 also provides the necessary signals to interface to microprocessor systems with or without Direct Memory Access (DMA) capabilities. In order to interface to a large number of commercially available floppy disk drives, the FDC permits software specification of the track stepping rate, the head load time, and the head unload time.

The pin configuration and internal block diagram of the 8272 is shown in Figure 6. Table 2 contains a description for each FDC interface pin.

### Floppy Disk Commands

The 8272 executes fifteen high-level disk interface commands:

Specify Write Data
Sense Drive Status Write Deleted Data
Sense Interrupt Status Read Track
Seek Read ID
Recalibrate Scan Equal
Format Track Scan High or Equal
Read Data Scan Low or Equal

Each command is initiated by a multi-byte transfer from the processor to the FDC (the transferred bytes contain command and parameter information). After complete command specification, the FDC automatically executes the command. The command result data (after execution of the command) may require a multi-byte transfer of status information back to the processor. It is convenient to consider each FDC command as consisting of the following three phases:

### COMMAND PHASE:

The executing program transfers to the FDC all the information required to perform a particular disk operation. The 8272 automatically enters the command phase after RESET and following the completion of the result phase (if any) of a previous command.

EXECUTION PHASE: The FDC performs the operation as instructed. The execution phase is entered immediately after the last command parameter is written to the FDC in the preceding command phase. The execution phase normally ends when the last data byte is transferred to/from the disk (signalled by the TC input to the FDC) or when an error occurs.

### RESULT PHASE:

After completion of the disk operation, status and other been all nomes done notes housekeeping information ent band ton a datam are made available to the sonie rosses been sel to processor. After the procand said self annual size essor reads this information. wheels at a conhappen been off needw be mand phase and is ready to mos redions tol riew accept another command.

Interface Registers of MRM and Mrd for 1250 as (for both FM and MRM or 250 as (for both FM and MRM)

To support information transfer between the FDC and In addition to the Main Status Register, the FDC conthe system processor, the 8272 contains two 8-bit tains four additional status registers (ST0, ST1, ST2, registers: the Main Status Register and the Data and ST3). These registers are only available during the FDC status information and may be accessed at any time. The Main Status Pegisters (Table 1) time. The Main Status Register (Table 4) provides the system processor with the status of each disk drive, the A sldsnd sin W status of the FDC, and the status of the processor interface. The Data Register (read/write) stores data, commands, parameters, and disk drive status information. The Data Register is used to program the FDC during the command phase and to obtain result information after completion of FDC operations. Data is read from, or written to, the FDC registers by the combination of the A0, RD, WR, and CS signals, as described in the Table 3. Control, Write precompensation output con-

laterrupt Request. Active-high signal indicating an 8272 interrupt service

Write Clock. 300 kHz (FM) or 1 MHz (MFM) write clock with a constant

trol during MFM mode. Specifies sarly, late, and normal timing signals

Clock. Signal phase 8 MHz clock (50% duty cycle).

Table 5, 8272 Command Set

Table 4. Main Status Register Bit Definitions

Bit Number	Symbol	Description
0 noisemola	D <sub>0</sub> B	Disk Drive 0 Busy. Disk Drive 0 is in the Seek mode.
1	D <sub>1</sub> B	Disk Drive 1 Busy. Disk Drive 1 is in the Seek mode.
	D <sub>2</sub> B	Disk Drive 2 Busy. Disk Drive 2 is in the Seek mode.
3 erit.	D <sub>3</sub> B	Disk Drive 3 Busy. Disk Drive 3 is in the Seek mode.
4 × 30	CD	FDC Busy. A read or write command is in process.
	NDM	Non-DMA Mode. The FDC is in the non-DMA mode when this bit is high. This bit is set only during the execution phase of commands in the non-DMA mode. Transition to a low level indicates that the execution phase has ended.
	Orders of control of the control of	Data Input/Output. Indicates the direction of a data transfer between the FDC and the Data Register. When DIO is high, data is read from the Data Register by the processor; when DIO is low, data is written from the processor to the Data Register.
	RQM	Request for Master. Indicates that the Data Register is ready to send data to, or receive data from, the processor.

### Command/Result Phases

Table 5 lists the 8272 command set. For each of the fifteen commands, command and result phase data transfers are listed. A list of abbreviations used in the table is given in Table 6, and the contents of the result status registers (ST0-ST3) are illustrated in Table 7.

The bytes of data which are sent to the 8272 during the command phase, and are read out of the 8272 in the result phase, must occur in the order shown in Table 5. That is, the command code must be sent first and the other bytes sent in the prescribed sequence. All bytes of the command and result phases must be read/written as described. After the last byte of data in the command phase is sent to the 8272 the execution phase automatically starts. In a similar fashion, when the last byte of data is read from the 8272 in the result phase,

the command is automatically ended and the 8272 is ready for a new command. A command may be aborted by simply raising the terminal count signal (pin 16). This is a convenient means of ensuring that the processor may always gain control of the 8272 (even if the disk system hangs up in an abnormal manner).

It is important to note that during the result phase all bytes shown in Table 5 must be read. The Read Data command, for example, has seven bytes of data in the result phase. All seven bytes must be read in order to successfully complete the Read Data command. The 8272 will not accept a new command until all seven bytes have been read. The number of command and result bytes varies from command-to-command.

In order to read data from, or write data to, the Data Register during the command and result phases, the system processor must examine the Main Status Register to determine if the Data Register is available. The DIO (bit 6) and RQM (bit 7) flags in the Main Status Register must be low and high, respectively, before each byte of the command word may be written into the 8272. Many of the commands require multiple bytes, and as a result, the Main Status Register must be read prior to each byte transfer to the 8272. To read status bytes during the result phase, DIO and ROM in the Main Status Register must both be high. Note, checking the Main Status Register in this manner before each byte transfer to/from the 8272 is required only in the command and result phases, and is NOT required during the execution phase.

### **Execution Phase**

All data transfers to (or from) the floppy drive occur during the execution phase. The 8272 has two primary modes of operation for data transfers (selected by the specify command):

- 1. DMA mode
- 2. non-DMA mode

In the DMA mode, DRQ (DMA Request) is activated for each transfer request. The DMA controller responds to DRQ with DACK (DMA Acknowledge) and RD (for read commands) or WR (for write commands). DRQ is reset by the FDC during the transfer. INT is activated after the last data transfer, indicating the completion of the execution phase, and the beginning of the result phase. In the DMA mode, the terminal count (TC/EOP) output of the DMA controller should be connected to the 8272 TC input to properly terminate disk data transfer commands.

In the non-DMA mode, transfer requests are indicated by activation of both the INT output signal and the ROM flag (bit 7) in the Main Status Register, INT can be used for interrupt-driven systems and ROM can be used for polled systems. The system processor must respond to the transfer request by reading data from (activating RD), or writing data to (activating WR), the FDC. This response removes the transfer request (INT and ROM are set inactive). After completing the last transfer, the 8272 activates the INT output to indicate the beginning of the result phase. In the non-DMA mode, the processor must activate the TC signal to the FDC (normally by means of an I/O port) after the transfer request for the last data byte has been received (by the processor) and before the appropriate data byte has been read from (or written to) the FDC.

In either mode of operation (DMA or non-DMA), the execution phase ends when a terminal count signal is sensed or when the last sector on a track (the EOT parameter—Table 5) has been read or written. In addition, if the disk drive is in a "not ready" state at the beginning of the execution phase, the "not ready" flag (bit 3 in Status Register 0) is set (high) and the command is terminated.

If a fault signal is received from the disk drive at the end of a write operation (Write Data, Write Deleted Data, or Format), the FDC sets the "equipment check" flag (bit 4 in Status Register 0), and terminates the command after setting the interrupt code (bits 7 and 6 of Status Register 0) to "01" (bit 7 low, bit 6 high).

### Multi-sector and Multi-track Transfers

During disk read/write transfers (Read Data, Write Data, Read Deleted Data, and Write Deleted Data), the FDC will continue to transfer data from sequential sectors until the TC input is sensed. In the DMA mode, the

TC input is normally connected to the TC/EOP (terminal count) output of the DMA controller. In the non-DMA mode, the processor directly controls the FDC TC input as previously described. Once the TC input is received, the FDC stops requesting data transfers (from the system processor or DMA controller). The FDC, however, continues to read data from, or write data to, the floppy disk until the end of the current disk sector. During a disk read operation, the data read from the disk (after reception of the TC input) is discarded, but the data CRC is checked for errors; during a disk write operation, the remainder of the sector is filled with all-zero bytes.

If the TC signal is not received before the last byte of the current sector has been transferred to/from the system, the FDC increments the sector number by one and initiates a read or write command for this new disk sector.

The FDC is also designed to operate in a multi-track mode for dual-sided disks. In the multi-track mode (specified by means of the MT flag in the command byte—Table 5) the FDC will automatically increment the head address (from 0 to 1) when the last sector (on the track under head 0) has been read or written. Reading or writing is then continued on the first sector (sector 1) of head 1.

### **Drive Status Polling**

After the power-on reset, the 8272 automatically enters a drive status polling mode. If a change in drive status is detected (all drives are assumed to be "not ready" at power-on), an interrupt is generated. The 8272 continues this status polling between command executions (and between step pulses in the Seek command). In this manner, the 8272 automatically notifies the system processor when a floppy disk is inserted, removed, or changed by the operator.

# **Command Details**

During the command phase, the Main Status Register must be polled by the CPU before each byte is written into the Data Register. The DIO (bit 6) and RQM (bit 7) flags in the Main Status Register must be low and high, respectively, before each byte of the command may be written into the 8272. The beginning of the execution phase for any of these commands will cause DIO to be set high and RQM to be set low.

The following paragraphs describe the fifteen FDC commands in detail.

# Specify

The Specify command is used prior to performing any commands for multiple dri disk operations (including the formatting of a new disk) to define drive/FDC operating characteristics. The Specify command parameters set the values for three internal timers:

- 1. Head Load Time (HLT) This seven-bit value defines the time interval that the FDC waits after loading the head before initiating a read or write operation. This timer is programmable from 2 to 254 milliseconds in increments of 2 ms. o sides a ground
- 2. Head Unload Time (HUT) This four-bit value defines the time from the end of the execution phase (of a read or write command) until the head is unloaded. This timer is programmable from 16 to 240 milliseconds in increments of 16 ms. If the processor issues another command before the head unloads, the head will remain loaded and the head load wait will be eliminated.
- 3. Step Rate Time (SRT) This four-bit value defines the time interval between step pulses issued by the FDC (track-to-track access time). This timer is programmable from 1 to 16 milliseconds in increments

The time intervals mentioned above are a direct function of the FDC clock (CLK on pin 19). Times indicated

The Specify command also indicates the choice of DMA or ion-DMA operation (by means of the ND bit). When waishit is high the non-DMA mode is selected; when ND is , the DMA mode is selected. Sse Drive Status

Tommand may be used by the processor whenever ihes to obtain the status of the disk drives. Status Jer 3 (returned during the result phase) contains ive status information as described in Table 7.

# Sense Interrupt Status

An interrupt signal is generated by the FDC when one or more of the following events occurs: 1. The FDC enters the result phase for:

- a. Read Data command and three a

  - b. Read Track command
- c. Read ID command
- d. Read Deleted Data command
- e. Write Data command
- f. Format Track command
- g. Write Deleted Data command h. Scan commands
- 2. The ready signal from one of the disk drives changes
- 3. A Seek or Recalibrate command completes opera-
- 4. The FDC requires a data transfer during the execution phase of a command in the non-DMA mode.

Interrupts caused by reasons (1) and (4) above occur during normal command operations and are easily discernible by the processor. However, interrupts caused by reasons (2) and (3) above are uniquely identified with the aid of the Sense Interrupt Status command. This command, when issued, resets the interrupt signal and by means of bits 5, 6, and 7 of Status Register 0 (returned during the result phase) identifies the cause of the interrupt (see Table 8). each step pulse is issued, the desired cylinder acc the step rate time (SET) in the Spe

Seek End	Interrup	. Inter	rupt Codes
0	Bit 6	Bit 7	Cause
	0.2 adi	0	Ready Line changed state, either polarity Normal Termination of Seek or Recalibrate Command

operating in the seek mode. When a drive has completed Neither the Seek nor the Recalibrate command has a result phase. Therefore, it is mandatory to use the Sense Interrupt Status Command after these commands to effectively terminate them and to provide verification of

When an interrupt is received by the processor, the FDC busy flag (bit 4) and the non-DMA flag (bit 5) may be used to distinguish the above interrupt causes:

- 0 Asynchronous event-(2) or (3) above
- 0 1 Result phase-(1) above
- 1 Data transfer required-(4) above

A single interrupt request to the processor may, in fact, be caused by more than one of the above events. The processor should continue to issue Sense Interrupt Status commands (and service the resulting conditions) until an invalid command code is received. In this manner, all "hidden" interrupts are serviced.

### Seek

The Seek command causes the drive's read/write head to be positioned over the specified cylinder. The FDC determines the difference between the current cylinder address and the desired (specified) address, and issues the appropriate number of step pulses. If the desired cylinder address is larger than the current address, the direction signal (LCT/DIR, pin 38) is set high (step-in); the direction signal is set low (step-out) if the desired cylinder address is less than the current address. No head movement occurs (no step pulses are issued) if the desired cylinder is the same as the current cylinder.

The rate at which step pulses are issued is controlled by the step rate time (SRT) in the Specify command. After each step pulse is issued, the desired cylinder address is compared against the current cylinder address. When the cylinder addresses are equal, the "seek end" flag (bit 5 in Status Register 0) is set (high) and the command is terminated. If the disk drive becomes "not ready" during the seek operation, the "not ready" flag (in Status Register 0) is set (high) and the command is terminated.

During the command phase of the Seek operation the FDC is in the FDC busy state, but during the execution phase it is in the non-busy state. While the FDC is in the non-busy state, another Seek command may be issued. In this manner parallel seek operations may be in operation on up to four floppy disk drives at once. The Main Status Register contains a flag for each drive (Table 4) that indicates whether the associated drive is currently operating in the seek mode. When a drive has completed a seek operation, the FDC generates an interrupt. In response to this interrupt, the system software must issue a Sense Interrupt Status command. During the result phase of this command, Status Register 0 (containing the drive number in bits 0 and 1) is read by the processor.

### Recalibrate

This command causes the read/write head of the disk drive to retract to the track 0 position. The FDC clears the contents of its internal cylinder counter, and checks the status of the track 0 signal from the disk drive. As long as the track 0 signal is low, the direction signal remains high and step pulses are issued. When the track 0 signal goes high, the seek end flag (in Status Register 0) is set (high) and the command is terminated. If the track 0 signal is still low after 77 step pulses have been issued, the seek end and equipment check flags (in Status Register 0) are both set and the Recalibrate command is terminated.

Recalibrate commands for multiple drives can be overlapped in the same manner that Seek commands are overlapped.

### Format Track ved tes set the same many of the State of th

The Format Track command formats or "initializes" a track on a floopy disk by writing the ID field, gaps, and address marks for each sector. Before issuing the Format command, the Seek command must be used to position the read/write head over the correct cylinder. In addition, a table of ID field values (cylinder, head, and sector addresses and sector length code) must be prepared before the command is executed. During command execution, the FDC accesses the table and, using the values supplied, writes each sector on the track. The ID field address mark originates from the FDC and is written automatically as the first byte of each sector's ID field. The cylinder, head, and sector addresses are taken, in order, from the table. The ID field CRC character (derived from the data written in the first five bytes) is written as the last two bytes of the ID field. Gaps are written automatically by the FDC, with the length of the variable gap determined by one of the Format command parameters.

The data field address mark is generated by the FDC and is written automatically as the first byte of the data field. The data pattern specified in the command phase is written into each data byte of each sector. A CRC character is derived from the data address mark and the data written in the sector's data field. The two CRC bytes are appended to the last data byte.

The formatting of a track begins at the physical index mark. As previously mentioned, the order of sector assignment is taken directly from the formatting table. Four entries are required for each sector: a cylinder address, a head address, a sector address, and a sector length code. The cylinder address in the ID field should be equal to the cylinder address of the track currently being formatted.

The sector addresses must be unique (no two equal). The order of the sector entries in the table is the sequence in which sector numbers appear on the track when it is formatted. The number of entry sets (cylinder, head, and sector address and sector length code) must equal the number of sectors allocated to the track (specified in the command phase).

Since the sector address is supplied, in order, for each sector, tracks can be formatted sequentially (the first sector following the index mark is assigned sector address 1, the adjacent sector is assigned sector address 2, and so on) or sector numbers can be interleaved (see section 3) on a track.

Table 9 lists recommended gap sizes and sectors/track for various sector sizes.

### Read Data

Nine (9) bytes are required to complete the command phase specification for the Read Data command. During the execution phase, the FDC loads the head (if it is in the unloaded state), waits the specified head load time (defined in the Specify command), and begins reading ID address marks and ID fields. When the requested sector address compares with the sector address read from the disk, the FDC outputs data (from the data field) byte-by-byte to the system. The Read Data command automatically operates in the multi-sector mode described earlier. In addition, multi-track operation may be specified by means of the MT command flag (Table 5). The amount of data that can be transferred with a single command to the FDC depends on the multi-track flag, the recording density flag, and the number of bytes per sector.

During the execution of read and write commands, the special sector size parameter (DTL) is used to temporarily alter the effective disk sector size. By setting the sector size code (N) to zero, DTL may be used to specify a sector size from 1 to 256 bytes in length. If the actual sector (on the disk) is larger than DTL specifies, only the number of bytes specified by the DTL parameter are

passed to the system; the remainder of the actual disk sector is not transferred (although the data is checked for CRC errors). Multi-sector read operations are performed in the same manner as they are when the sector size code is non-zero. (The N and DTL parameters are always present in the command sequence. DTL should be set to FF hexadecimal when N is not zero.)

If the FDC detects the physical index mark twice without finding the requested sector, the FDC sets the "sector not found error" flag (bit 2 in Status Register 1) and terminates the Read Data command. The interrupt code (bits 7 and 6 of Status Register 0) is set to "01." Note that the FDC searches for each sector in a multisector operation. Therefore, a "sector not found" error may occur after successful transfer of one or more preceding sectors. This error could occur if a particular sector number was not included when the track was first formatted or if a hard error on the disk has invalidated a sector ID field.

After reading the ID field and data field in each sector, the FDC checks the CRC bytes. If a read error is detected (incorrect CRC in the ID field), the FDC sets the "data error" flag in Status Register 1; if a CRC error occurs in the data field, the FDC sets the "data error" flag in Status Register 2. In either error condition, the FDC terminates the Read Data command. The interrupt code (bits 7 and 6 in Status Register 0) is set to "01."

If the FDC reads a deleted data address mark from the disk, and the skip flag (specified during the command phase) is not set, the FDC sets the "control mark" flag (bit 6 in Status Register 2) and terminates the Read Data command (after reading all the data in the sector). If the skip flag is set, the FDC skips the sector with the deleted data address mark and reads the next sector. Thus, the skip flag may be used to cause the FDC to ignore deleted data sectors during a multi-sector read operation.

During disk data transfers between the FDC and the system, the FDC must be serviced by the system (processor or DMA controller) every 27  $\mu$ s in the FM mode, and every 13  $\mu$ s in the MFM mode. If the FDC is not

Notes: 1. Suggested values of GPL in Read or Write commands to avoid splice point between data field and ID field of contiguous sectors.

2. Suggested values of GPL in Format command. Animost and the strain and the stra

serviced within this interval, the "overrun error" flag (bit 4 in Status Register 1) is set and the Read Data command is terminated.

If the processor terminates a read (or write) operation in the FDC, the ID information in the result phase is dependent upon the state of the multi-track flag and end of track byte. Table 11 shows the values for C, H, R, and N, when the processor terminates the command.

### Write Data and place of the Data and Data of the State of the Write Data

Nine (9) bytes are required to complete the command phase specification for the Write Data command. During the execution phase the FDC loads the head (if it is in the unloaded state), waits the specified head load time (defined by the Specify command), and begins reading sector ID fields. When the requested sector address compares with the sector address read from the disk, the FDC reads data from the processor one byte at a time via the data bus and outputs the data to the data field of that sector. The CRC is computed on this data and two CRC bytes are written at the end of the data field.

The FDC reads the ID field of each sector and checks the CRC bytes. If the FDC detects a read error (incorrect CRC) in one of the ID fields, it sets the "data error" flag (bit 5 in Status Register 1) and terminates the Write Data command. The interrupt code (bits 7 and 6 in Status Register 0) is set to "01."

The Write Data command operates in much the same manner as the Read Data command. The following items are the same; refer to the Read Data command for details:

- Multi-sector and Multi-track operation
- Data transfer capacity
- "End of track error" flag
- "Sector not found error" flag
- · "Data error" flag and analyzant stab stab gained
- Head unload time interval
- ID information when the processor terminates the command (see Table 11)
- Definition of DTL when N=0 and when  $N\neq 0$

During the Write Data execution phase, data transfers between the processor and FDC must occur every  $31 \mu s$  in the FM mode, and every  $15 \mu s$  in the MFM mode. If the time interval between data transfers is longer than this, the FDC sets the "overrun error" flag (bit 4 in Status Register 1) and terminates the Write Data command.

### Read Deleted Data

This command operates in almost the same manner as the Read Data command operates. The only difference involves the treatment of the data address mark and the skip flag. When the FDC detects a data address mark at the beginning of a data field (and the skip flag is not set), the FDC reads all the data in the sector, sets the "control mark" flag (bit 6 in Status Register 2), and terminates the command. If the skip flag is set, the FDC skips the sector with the data address mark and continues reading at the next sector. Thus, the skip flag may be used to cause the FDC to read only deleted data sectors during a multi-sector read operation.

# Write Deleted Data

This command operates in the same manner as the Write Data command operates except that a deleted data address mark is written at the beginning of the data field instead of the normal data address mark. This command is used to mark a bad sector (containing a hard error) on the floppy disk.

### **Read Track**

The Read Track command is similar to the Read Data command except that the entire data field is read continuously from each of the sectors of a track. Immediately after encountering the physical index mark, the FDC starts reading all data fields on the track as continuous blocks of data. If the FDC finds an error in the ID field or data field CRC check bytes, it continues to read data from the track. The FDC compares the ID information read from each sector with the values specified during the command phase. If the specified ID field information is not found on the track, the "sector not found error" flag (in Status Register 1) is set. Multitrack and skip operations are not allowed with this command.

This command terminates when the last sector on the track has been read. (The number of sectors on the track is specified by the end of track parameter byte during the command phase.) If the FDC does not find an ID address mark on the disk after it encounters the physical index mark for the second time, it sets the "missing address mark error" flag (bit 0 in Status Register 1) and terminates the command. The interrupt code (bits 7 and 6 of Status Register 0) is set to "01."

### Read ID

The Read ID command transfers (reads) the first correct ID field from the current disk track (following the physical index mark) to the processor. If no correct ID address mark is found on the track, the "missing address mark error" flag is set (bit 0 in Status Register 1). If no data mark is found on the track, the "sector not found error" flag is also set (bit 2 in Status Register 1). Either error condition causes the command to be terminated.

### Scan Commands TARAGES ATAC EHT .a

The Scan commands allow the data being read from the disk to be compared against data supplied by the system (by the processor in non-DMA mode, and by the DMA controller in DMA mode). The FDC compares the data on a byte-by-byte basis, and searches for a sector of data that meets the conditions of "disk data equal to system data", "disk data less than or equal to system data", or "disk data greater than or equal to system data". Simple binary (ones complement) arithmetic is used for comparison (FF = largest number, 00 = smallest number). If, after a complete sector of data is compared, the conditions are not met, the sector number is incremented by the scan sector increment (specified in the command phase), and the scan operation is continued. The scan operation continues until one of the following conditions occurs; the conditions for scan are met (equal, low, or high), the last sector on the track is reached, or the terminal count signal is received.

If the conditions for scan are met, the FDC sets the "scan hit" flag (bit 3 in Status Register 2) and terminates the Scan command. If the conditions for scan are not met between the starting sector and the last sector on the track (specified in the command phase), the FDC sets the "scan not satisfied" flag (bit 2 in Status Register 2) and terminates the Scan command. The receipt of a terminal count signal from the processor or DMA controller during the scan operation will cause the FDC to complete the comparison of the particular byte which is in process, and to terminate the command. Table 10 shows the status of the "scan hit" and "scan

not satisfied" flags under various scan termination conditions.

If the FDC encounters a deleted data address mark in one of the sectors and the skip flag is low, it regards the sector as the last sector on the cylinder, sets the "control mark" flag (bit 6 in Status Register 2) and terminates the command. If the skip flag is high, the FDC skips the sector with the deleted address mark, and reads the next sector. In this case, the FDC also sets the "control mark" flag (bit 6 in Status Register 2) in order to show that a deleted sector had been encountered.

NOTE: During scan command execution, the last sector on the track must be read for the command to terminate properly. For example, if the scan sector increment is set to 2, the end of track parameter is set to 26, and the scan begins at sector 21, sectors 21, 23, and 25 will be scanned. The next sector, 27 will not be found on the track and an abnormal command termination will occur. The command would be completed in a normal manner if either a) the scan had started at sector 20 or b) the end of track parameter had been set to 25.

During the Scan command, data is supplied by the processor or DMA controller for comparison against the data read from the disk. In order to avoid having the "overrun error" flag set (bit 4 in Status Register 1), it is necessary to have the data available in less than 27  $\mu$ s (FM Mode) or 13  $\mu$ s (MFM Mode). If an overrun error occurs, the FDC terminates the command.

### **Invalid Commands**

If an invalid (undefined) command is sent to the FDC, the FDC will terminate the command. No interrupt is generated by the 8272 during this condition. Bit 6 and bit 7 (DIO and RQM) in the Main Status Register are both set indicating to the processor that the 8272 is in the result phase and the contents of Status Register 0 must be read. When the processor reads Status Register 0 it will find an 80H code indicating that an invalid command was received.

A Sense Interrupt Status command must be sent after a Seek or Recalibrate interrupt; otherwise the FDC will consider the next command to be an invalid command. Also, when the last "hidden" interrupt has been serviced, further Sense Interrupt Status commands will result in invalid command codes.

In some applications the user may wish to use this command as a No-Op command to place the FDC in a stand-by or no operation state.

### 5. THE DATA SEPARATOR

As briefly discussed in section 2, LSI disk controllers such as the 8272 require external circuitry to generate a data window signal. This signal is used within the FDC to isolate the data bits contained within the READ DATA input signal from the disk drive. (The disk READ DATA signal is a composite signal constructed from both clock and data information.) After isolating the data bits from this input signal, the FDC assembles the data bits into 8-bit bytes for transfer to the system processor or memory.

### Single Density and too ere anoitibno ed being

In single-density (FM) recording (Figure 3), the bit cell is 4 microseconds wide. Each bit cell contains a clock bit at the leading edge of the cell. The data bit (if present) is always located at the center of the cell. The job of data separation is relatively straightforward for single-density; simply generate a data window  $2 \mu s$  wide starting  $1 \mu s$  after each clock bit. Since every cell has a clock bit, a fixed window reference is available for every data bit and because the window is  $2 \mu s$  wide, a slightly shifted data bit will still remain within the data window.

A single-density data separator with these specifications may be easily generated using a digital or analog oneshot triggered by the clock bit.

### **Double-Density**

Double-density (MFM) bit cells are reduced to 2  $\mu$ s (in order to double the disk data storage capacity). Clock bits are inserted into the data stream only if data bits are not present in both the current and preceding bit cells (Figure 3). The data bit (if present) still occurs at the center of the bit cell and the clock bit (if present) still occurs at the leading edge of the bit cell.

MFM data separation has two problems. First, only some bit cells contain a clock bit. In this manner, MFM encoding loses the fixed bit cell reference pulse present in FM encoding. Second, the bit cell for MFM is one-half the size of the bit cell for FM. This shorter bit cell means that MFM cannot tolerate as large a playback data-shift (as FM can tolerate) without errors.

Since most playback data-shift is predictable, the FDC can precompensate the write data stream so that data/clock pulses will be correctly positioned for subsequent playback. This function is completely controlled by the FDC and is only required for MFM recording. During write operations, the FDC specifies an early, normal, or late bit positioning. This timing information is specified with respect to the FDC write clock. Early and late timing is typically 125 ns to 250 ns before or after the write clock transition (depending on disk drive requirements).

The data separator circuitry for double-density recording must continuously analyze the total READ DATA stream, synchronizing its operation (window generation) with the actual clock/data bits of the data stream. The data separation circuit must track the disk input data frequency very closely—unpredictable bit shifts leave less than 50 ns margin to the window edges.

### Phase-Locked Loop

Only an analog phase-locked loop (PLL) can provide the reliability required for a double-density data separation circuit. (A phase-locked loop is an electronic circuit that constantly analyzes the frequency of an input signal and locks another oscillator to that frequency.) Using analog PLL techniques, a data separator can be designed with ±1 ns resolution (this would require a 100 MHz clock in a digital phase-locked loop). The analog PLL determines the clock and data bit positions by sampling each bit in the serial data stream. The phase relationship between a data bit and the PLL generated data window is constantly fed back to adjust the position of the data window, enabling the PLL to track input data frequency changes, and thereby reliably read previously recorded data from a floppy disk.

### PLL Design

A block diagram of the phase-locked loop described in this application note is shown in Figure 7. Basically, the phase-locked loop operates by comparing the frequency of the input data (from the disk drive) against the frequency of a local oscillator. The difference of these frequencies is used to increase or decrease the frequency of the local oscillator in order to bring its frequency closer to that of the input. The PLL synchronizes the local oscillator to the frequency of the input during the all "zeroes" synchronization field on the floppy disk (immediately preceding both the ID field and the data field).

The PLL consists of nine ICs and is located on page 3 of the schematics in the Appendix. The 8272 VCO output essentially turns the PLL circuitry on and off. When the PLL is off, it "idles" at its center frequency. The VCO output turns the PLL on only when valid data is being received from the disk drive. The VCO turns the PLL on after the read/write head has been loaded and the head load time has elapsed. The PLL is turned off in the gap between the ID field and the data field and in the gap after the data field (before the next sector ID field). The GPL parameter in the FDC read and write commands specifies the elapsed time (number of data bytes) that the PLL is turned off in order to blank out discontinuities that appear in the gaps when the write current is turned on and off. The PLL operates with either MFM or FM input data. The MFM output from the FDC controls the PLL operation frequency.

The PLL consists of six functional blocks as follows:

- Pulse Shaping A 96LS02 senses a READ DATA pulse and provides a clean output signal to the FDC and to the PLL Phase Comparator and Frequency Discriminator circuitry.
- 2. Phase Comparator The phase difference between the PLL oscillator and the READ DATA input is compared. Pump up (PU) and pump down (PD) error signals are derived from this phase difference and output to the filter. If there is no phase difference between the PLL oscillator and the READ DATA input, the PU and PD pulse widths are equal. If the READ DATA pulse occurs early, the PU duration is shorter than the PD duration. If the data pulse occurs late, the PU duration is longer than the PD duration.
- Filter This analog circuit filters the PU and PD pulses into an error voltage. This error voltage is buffered by an LM358 operational amplifier.

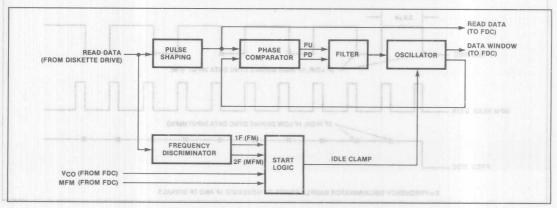

Figure 7. Phase-Locked Loop Data Separator

2-155 AFN 01795A

- 74LS393, 74LS74, and 96LS02. The oscillator frequency is controlled by the error voltage output by the filter. This oscillator also generates the data window signal to the FDC.
- Frequency Discriminator This logic tracks the READ DATA input from the disk drive and discriminates between the synchronization gap for FM recording (250 KHz) and the gap for MFM recording (500 KHz). Synchronization gaps immediately precede address marks.
- 6. Start Logic The function of this logic is to clamp the PLL oscillator to its center frequency (2 MHz) until the FDC VCO signal is enabled and a valid data pattern is sensed by the frequency discriminator. The start logic (consisting of a 74LS393 and 74LS74) ensures that the PLL oscillator is started with zero phase error.

# PLL Adjustments

The PLL must be initially adjusted to operate at its center frequency with the VCO output off and the adjustment jumper removed. The 5K trimpot should be adjusted until the frequency at the test point (Q output of the 96LS02) is 2 MHz. The jumper should then be replaced for normal operation.

### PLL Design Details bas U9 and Jugan ATAG

The following paragraphs describe the operational and design details of the phase-locked loop data separator il-

in the appendix. Note that the analog section is operated from a separately filtered +5V supply.

### Initialization o said sisb \\ doctor lauros ord risiw (nois

As long as the 8272 maintains a low VCO signal, the data separator logic is "turned off". In this state, the PLL oscillator (96LS02) is not oscillating and therefore the 2XBR signal is constantly low. In addition, the pump up (PU) and pump down (PD) signals are inactive (PU low and PD high), the CNT8 signal is inactive (low), and the filter input voltage is held at 2.5 volts by two 1Mohm resistors between ground and +5 volts.

### Floppy Disk Data or rotallisso rantons about birs

The data separator frequency discriminator, the input pulse shaping circuitry, and the start logic are always enabled and respond to rising edges of the READ DATA signal. The rising edge of every data bit from the disk drive triggers two pulse shaping one-shots. The first pulse shaper generates a stable and well-defined 200 ns read data pulse for input to the 8272 and other portions of the data separator logic. The second one-shot generates a 2.5  $\mu$ s data pulse that is used for input data frequency discrimination.

The frequency discriminator operates as illustrated in Figure 8. The 2F output signal is active (high) during reception of valid MFM (double-density) sync fields on the disk while the 1F signal is active (high) during reception of valid FM (single-density) sync fields. A multiplexer (controlled by the 8272 MFM signal) selects the appropriate 1F or 2F signal depending on the programmed mode.

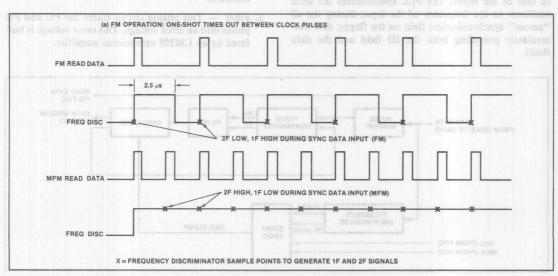

Figure 8. Input Data Frequency Discrimination

### Startup

The data separator is designed to require reception of eight valid sync bits (one sync byte) before enabling the PLL oscillator and attempting to synchronize with the input data stream (see Figure 9). This delay ensures that the PLL will not erroneously synchronize outside a valid sync field in the data stream if the VCO signal is enabled slightly early. The sync bit counter is asynchronously reset by the CNTEN signal when valid sync data is not being received by the drive.

Processor and Memory

Once the VCO signal is active and eight sync bits have been counted, the CNT8 signal is enabled. This signal turns on the PLL oscillator. Note that this oscillator starts synchronously with the rising edge of the disk input data (because CNT8 is synchronous with the data rising edge) and the oscillator also starts at its center frequency of 2 MHz (because the LM348 filter input is held at its center voltage of approximately 2.5 volts). This frequency is divided by two and four to generate the 2XBR signal (1 MHz for MFM and 500 KHz for FM).

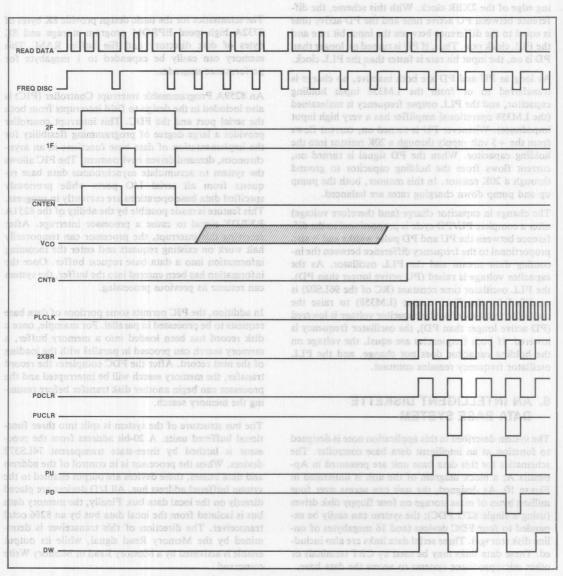

Figure 9. Typical Data Separator Startup Timing Diagram

2-157

### PLL Synchronization al langia OOV and sonO

At this point, the PLL is enabled and begins to synchronize with the input data stream. This synchronization is accomplished very simply in the following manner. The pump up (PU) signal is enabled on the rising edge of the READ DATA from the disk drive. (When the PLL is synchronized with the data stream, this point will occur at the same time as the falling edge of the 2XBR signal as shown in Figure 9). The PU signal is turned off and the PD signal is activated on the next rising edge of the 2XBR clock. With this scheme, the difference between PU active time and the PD active time is equal to the difference between the input bit rate and the PLL clock rate. Thus, if PU is turned on longer than PD is on, the input bit rate is faster than the PLL clock.

As long as PU and PD are both inactive, no charge is transferred to or from the LM358 input holding capacitor, and the PLL output frequency is maintained (the LM358 operational amplifier has a very high input impedance). Whenever PU is turned on, current flows from the +5 volt supply through a 20K resistor into the holding capacitor. When the PD signal is turned on, current flows from the holding capacitor to ground through a 20K resistor. In this manner, both the pump up and pump down charging rates are balanced.

The change in capacitor charge (and therefore voltage) after a complete PU/PD cycle is proportional to the difference between the PU and PD pulse widths and is also proportional to the frequency difference between the incoming data stream and the PLL oscillator. As the capacitor voltage is raised (PU active longer than PD), the PLL oscillator time constant (RC of the 96LS02) is modified by the filter output (LM358) to raise the oscillator frequency. As the capacitor voltage is lowered (PD active longer than PD), the oscillator frequency is lowered. If both frequencies are equal, the voltage on the holding capacitor does not change, and the PLL oscillator frequency remains constant.

# 6. AN INTELLIGENT DISKETTE DATA BASE SYSTEM

The system described in this application note is designed to function as an intelligent data base controller. The schematics for this data base unit are presented in Appendix A; a block diagram of the unit is illustrated in Figure 10. As designed, the unit can access over four million bytes of mass storage on four floppy disk drives (using a single 8272 FDC); the system can easily be expanded to four FDC devices (and 16 megabytes of online disk storage). Three serial data links are also included. These data links may be used by CRT terminals or other microprocessor systems to access the data base.

### **Processor and Memory**

A high-performance 8088 eight-bit microprocessor (operating at 5 MHz with no wait states) controls system operation. The 8088 was selected because of its memory addressing capabilities and its sophisticated string handling instructions. These features improve the speed of data base search operations. In addition, these capabilities allow the system to be easily upgraded with additional memory, disk drives, and if required, a bubble memory or winchester disk unit.

The schematics for the basic design provide 8K bytes of 2732A high-speed EPROM program storage and 8K bytes of disk directory and file buffer RAM. This memory can easily be expanded to 1 megabyte for performance upgrades.

An 8259A Programmable Interrupt Controller (PIC) is also included in the design to field interrupts from both the serial port and the FDC. This interrupt controller provides a large degree of programming flexibility for the implementation of data base functions in an asynchronous, demand driven environment. The PIC allows the system to accumulate asynchronous data base requests from all serial I/O ports while previously specified data base operations are currently in progress. This feature is made possible by the ability of the 8251A RXRDY signal to cause a processor interrupt. After receiving this interrupt, the processor can temporarily halt work on existing requests and enter the incoming information into a data base request buffer. Once the information has been entered into the buffer, the system can resume its previous processing.

In addition, the PIC permits some portions of data base requests to be processed in parallel. For example, once a disk record has been loaded into a memory buffer, a memory search can proceed in parallel with the loading of the next record. After the FDC completes the record transfer, the memory search will be interrupted and the processor can begin another disk transfer before resuming the memory search.

The bus structure of the system is split into three functional buffered units. A 20-bit address from the processor is latched by three-state transparent 74LS373 devices. When the processor is in control of the address and data busses, these devices are output enabled to the system buffered address bus. All I/O devices are placed directly on the local data bus. Finally, the memory data bus is isolated from the local data bus by an 8286 octal transceiver. The direction of this transceiver is determined by the Memory Read signal, while its output enable is activated by a Memory Read or Memory Write command.

Floure 9. Typical Data Separator Startup Timing Diagram

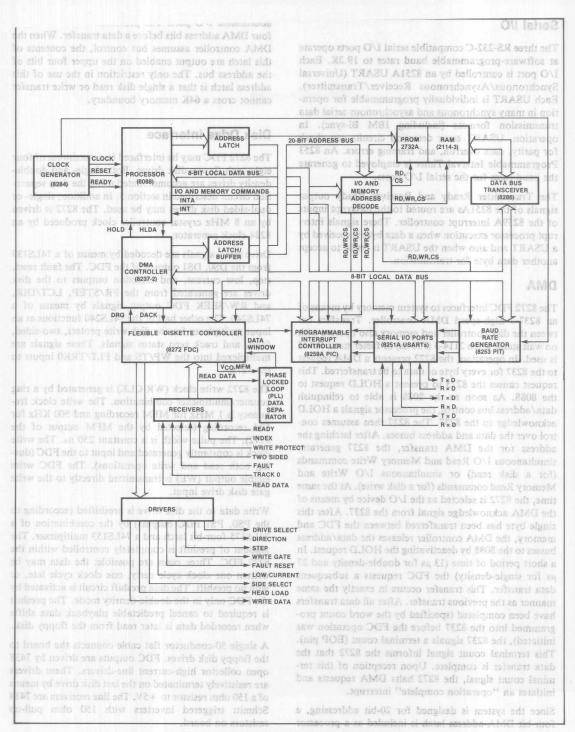

Figure 10. Intelligent Data Base Block Diagram

The three RS-232-C compatible serial I/O ports operate at software-programmable baud rates to 19.2K. Each I/O port is controlled by an 8251A USART (Universal Synchronous/Asynchronous Receiver/Transmitter). Each USART is individually programmable for operation in many synchronous and asynchronous serial data transmission formats (including IBM Bi-sync). In operation, USART error detection circuits can check for parity, data overrun, and framing errors. An 8253 Programmable Interval Timer is employed to generate the baud rates for the serial I/O ports.

The Transmitter Ready and Receiver Ready output signals of the 8251As are routed to the interrupt inputs of the 8259A interrupt controller. These signals interrupt processor execution when a data byte is received by a USART and also when the USART is ready to accept another data byte for transmission.

### DMA

The 8272 FDC interfaces to system memory by means of an 8237-2 high-speed DMA controller. Transfers between the disk controller and memory also operate with no wait states when 2114-3 (150 ns) or faster static RAM is used. In operation, the 8272 presents a DMA request to the 8237 for every byte of data to be transferred. This request causes the 8273 to present a HOLD request to the 8088. As soon as the 8088 is able to relinquish data/address bus control, the processor signals a HOLD acknowledge to the 8237. The 8237 then assumes control over the data and address busses. After latching the address for the DMA transfer, the 8237 generates simultaneous I/O Read and Memory Write commands (for a disk read) or simultaneous I/O Write and Memory Read commands (for a disk write). At the same time, the 8272 is selected as the I/O device by means of the DMA acknowledge signal from the 8237. After this single byte has been transferred between the FDC and memory, the DMA controller releases the data/address busses to the 8088 by deactivating the HOLD request. In a short period of time (13 µs for double-density and 27 us for single-density) the FDC requests a subsequent data transfer. This transfer occurs in exactly the same manner as the previous transfer. After all data transfers have been completed (specified by the word count programmed into the 8237 before the FDC operation was initiated), the 8237 signals a terminal count (EOP pin). This terminal count signal informs the 8272 that the data transfer is complete. Upon reception of this terminal count signal, the 8272 halts DMA requests and initiates an "operation complete" interrupt.

Since the system is designed for 20-bit addressing, a four-bit DMA-address latch is included as a processor

four DMA address bits before a data transfer. When the DMA controller assumes bus control, the contents of this latch are output enabled on the upper four bits of the address bus. The only restriction in the use of this address latch is that a single disk read or write transfer cannot cross a 64K memory boundary.

### **Disk Drive Interface**

The 8272 FDC may be interfaced to a maximum of four eight-inch floppy disk drives. Both single- and double-density drives are accommodated using the data separation circuit described in section 5. In addition, single- or dual-sided disk drives may be used. The 8272 is driven by an 8 MHz crystal controller clock produced by an 8224 clock generator.

Drive select signals are decoded by means of a 74LS139 from the DS0, DS1 outputs of the FDC. The fault reset, step, low current, and direction outputs to the disk drives are generated from the FR/STEP, LCT/DIR, and RW/SEEK FDC output signals by means of a 74LS240. The other half of the 74LS240 functions as an input multiplexer for the disk write protect, two-sided, fault, and track zero status signals. These signals are multiplexed into the WP/TS and FLT/TRK0 inputs to the 8272.

The 8272 write clock (WR CLK) is generated by a ring counter/multiplexer combination. The write clock frequency is 1 MHz for MFM recording and 500 KHz for FM recording (selected by the MFM output of the 8272). The pulse width is a constant 250 ns. The write clock is constantly generated and input to the FDC (during both read and write operations). The FDC write enable output (WE) is transmitted directly to the write gate disk drive input.

Write data to the disk drive is preshifted (according to the PS0, PS1 FDC outputs) by the combination of a 74LS175 four-bit latch and a 74LS153 multiplexer. The amount of preshift is completely controlled within the 8272 FDC. Three cases are possible: the data may be written one clock cycle early, one clock cycle late, or with no preshift. The data preshift circuit is activated by the FDC only in the double-density mode. The preshift is required to cancel predictable playback data shifts when recorded data is later read from the floppy disk.

A single 50-conductor flat cable connects the board to the floppy disk drives. FDC outputs are driven by 7438 open collector high-current line-drivers. These drivers are resistively terminated on the last disk drive by means of a 150 ohm resistor to +5V. The line receivers are 7414 Schmitt triggered inverters with 150 ohm pull-up resistors on board.

2-160 AFN 01795A

### 7. SPECIAL CONSIDERATIONS

This section contains a quick review of key features and issues, most of which have been mentioned in other sections of this application note. Before designing with the 8272 FDC, it is advisable that the information in this section be completely understood. bad track operation, assume that a

### 1. Multi-Sector Transfers 1 bns 12 Joseph land comm

The 8272 always operates in a multi-sector transfer mode. The 8272 continues to transfer data until the TC input is activated. In a DMA configuration, the TC input of the 8272 must always be connected to the EOP/TC output of the DMA controller. When multiple DMA channels are used on a single DMA controller, EOP must be gated with the select signal for the proper FDC. If the TC signal is not gated, a terminal count on another channel will abort FDC operation.

In a processor driven configuration with no DMA controller, the system must count the transfers and supply a TC signal to the FDC. In a DMA environment, ORing a programmable TC with the TC from the DMA controller is a convenient means of ensuring that the processor may always gain control of the FDC (even if the diskette system hangs up in an abnormal manner).

#### 2. Processor Command/Result Phase Interface

In the command phase, the processor must write the exact number of parameters in the exact order shown in Table 5. During the result phase, the processor must read the complete result status. For example, the Format Track command requires six command bytes and presents seven result bytes. The 8272 will not accept a new command until all result bytes are read. Note that the number of command and result bytes varies from command-to-command. Command and result phases cannot be shortened. (16 viernam , de bas 0 noowing

During both the command and result phases, the Main Status Register must be read by the processor before each byte of information is read from, or written to, the FDC Data Register. Before each command byte is written, DIO (bit 6) must be low (indicating a data transfer from the processor) and RQM (bit 7) must be high (indicating that the FDC is ready for data). During the result phase, DIO must be high (indicating a data transfer to the processor) and ROM must also be high (indicating that data is ready for the processor).

NOTE: After the 8272 receives a command byte, the RQM flag may remain set for 12 microseconds (with an 8 MHz clock). Software should not attempt to read the Main Status Register before this time interval has elapsed; otherwise, the software will erroneously assume that the FDC is ready to accept the next byte.

### 3. Sector Sizes

The 8272 does not support 128 byte sectors in the MFM (double-density) mode. semmoo send T abnammoo masa

### 4. Write Clock

The FDC Write Clock input (WR CLK) must be present at all times.

the FDC may be reporting one of two distinteen s. The FDC Reset input (RST) must be held active during power-on reset while the RD and WR inputs are active. If the reset input becomes inactive while RD and WR are still active, the 8272 enters the test mode. Once activated, the test mode can only be deactivated by a power-down condition. Dissum as to additation at

### 6. Drive Status vo distinguished by subsection of the state of the sta

The 8272 constantly polls (starting after the power-on reset) all drives for changes in the drive ready status. At power-on, the FDC assumes that all drives are not ready. If a drive application requires that the ready line be strapped active, the FDC will generate an interrupt immediately after power is applied.

## 7. Gap Length was to sunitate to the processor and

Only the gap 3 size is software programmable. All other gap sizes are fixed. In addition, different gap 3 sizes must be specified in format, read, write, and scan commands. Refer to Section 3 and Table 9 for gap size recommendations.

### 8. Seek Command

The drive busy flag in the Main Status Register remains set after a Seek command is issued until the Sense Interrupt Status command is issued (following reception of the seek complete interrupt).

The FDC does not perform implied seeks. Before issuing data read or write commands, the read/write head must be positioned over the correct cylinder. If the head is not positioned correctly, a cylinder address error is data in the sector) when a deleted data addr.

After issuing a step pulse, the 8272 resumes drive status polling. For correct stepper operation in this mode, the stepper motor must be constantly enabled. (Most drives provide a jumper to permit the stepper motor to be constantly enabled.) b tady more noiteurs enzogo and taus

### 9. Step Rate Alam worlds stab a penW independent

The 8272 can emit a step pulse that is one millisecond faster than the rate programmed by the SRT parameter in the Specify command. This action may cause subsequent sector not found errors. The step rate time should be programmed to be 1 ms longer than the step rate time required by the drive.

#### 10. Cable Length

A cable length of less than 10 feet is recommended for drive interfacing.

### 11. Scan Commands

The current 8272 has several problems when using the scan commands. These commands should not be used at this time.

### 12. Interrupts

When the processor receives an interrupt from the FDC, the FDC may be reporting one of two distinct events:

- a) The beginning of the result phase of a previously requested read, write, or scan command.
- b) An asynchronous event such as a seek/recalibrate completion, an attention, an abnormal command termination, or an invalid command.

These two cases are distinguished by the FDC busy flag (bit 4) in the Main Status Register. If the FDC busy flag is high, the interrupt is of type (a). If the FDC busy flag is low, the interrupt was caused by an asynchronous event (b).

A single interrupt from the FDC may signal more than one of the above events. After receiving an interrupt, the processor must continue to issue Sense Interrupt Status commands (and service the resulting conditions) until an invalid command code is received. In this manner, all "hidden" interrupts are ferreted out and serviced.

### 13. Skip Flag (SK)

The skip flag is used during the execution of Read Data, Read Deleted Data, Read Track, and various Scan commands. This flag permits the FDC to skip unwanted sectors on a disk track.

When performing a Read Data, Read Track, or Scan command, a high SK flag indicates that the FDC is to skip over (not transfer) any sector containing a deleted data address mark. A low SK flag indicates that the FDC is to terminate the command (after reading all the data in the sector) when a deleted data address mark is encountered.

When performing a Read Deleted Data command, a high SK flag indicates that sectors containing normal data address marks are to be skipped. Note that this is just the opposite situation from that described in the last paragraph. When a data address mark is encountered during a Read Deleted Data command (and the SK flag

be programmed to be I ms longer than the step rate time

is low), the FDC terminates the command after reading all the data in the sector.

## 14. Bad Track Maintenance

The 8272 does not internally maintain bad track information. The maintenance of this information must be performed by system software. As an example of typical bad track operation, assume that a media test determines that track 31 and track 66 of a given floppy disk are bad. When the disk is formatted for use, the system software formats physical track 0 as logical cylinder 0 (C=0 in the command phase parameters), physical track 1 as logical track 1 (C=1), and so on, until physical track 30 is formatted as logical cylinder 30 (C=30). Physical track 31 is bad and should be formatted as logical cylinder FF (indicating a bad track). Next, physical track 32 is formatted as logical cylinder 31, and so on, until physical track 67 is formatted as logical cylinder 64. Next, bad physical track 66 is formatted as logical cylinder FF (another bad track marker), and physical track 67 is formatted as logical cylinder 65. This formatting continues until the last physical track (77) is formatted as logical cylinder 75. Normally, after this formatting is complete, the bad track information is stored in a prespecified area on the floppy disk (typically in a sector on track 0) so that the system will be able to recreate the bad track information when the disk is removed from the drive and reinserted at some later time.

To illustrate how the system software performs a transfer operation disk with bad tracks, assume that the disk drive head is positioned at track 0 and the disk described above is loaded into the drive. If a command to read track 36 is issued by an application program, the system software translates this read command into a seek to physical track 37 (since there is one bad track between 0 and 36, namely 31) followed by a read of logical cylinder 36. Thus, the cylinder parameter C is set to 37 for the Seek command and 36 for the Read Sector command.

### 15. Head Load versus Head Settle Times

The 8272 does not permit separate specification of the head load time and the head settle time. When the Specify command is issued for a given disk drive, the proper value for the HLT parameter is the maximum of the head load time and the head settle time.

## 1. Introduction

Disk interface software is a major contributor to the efficient and reliable operation of a floppy disk subsystem. This software must be a well-designed compromise between the needs of the application software modules and the capabilities of the floppy disk controller (FDC). In an effort to meet these requirements, the implementation of disk interface software is often divided into several levels of abstraction. The purpose of this application note is to define these software interface levels and describe the design and implementation of a modular and flexible software driver for the 8272 FDC. This note is a companion to AP-116, "An Intelligent Data Base System Using the 8272."

APPENDIX A-8272 FOC

## The Physical Interface Level

The software interface level closest to the FDC hardware is referred to as the physical interface level. At this level, interface modules (often called disk drivers or disk handlers) communicate directly with the FDC device. Disk drivers accept floppy disk commands from other software modules, control and monitor the FDC execution of the commands, and finally return operational status information (at command termination) to the requesting modules.

In order to perform these functions, the drivers must support the bit/byte level FDC interface for status and data transfers. In addition, the drivers must field, classify, and service a variety of FDC interrupts.

### The Logical Interface Level

System and application software modules often specify disk operation parameters that are not directly compatible with the FDC device. This software incompatibility is typically caused by one of the following:

- The change from an existing FDC to a functionally equivalent design. Replacing a TTL based controller with an LSI device is an example of a change that may result in software incompatibilities.
- 2. The upgrade of an existing FDC subsystem to a higher capability design. An expansion from a single-sided, single-density system to a dual-sided, double-density system to increase data storage capacity is an example of such a system change.
- 3. The abstraction of the disk software interface to avoid redundancy. Many FDC parameters (in particular the density, gap size, number of sectors per track and number of bytes per sector) are fixed for a floppy disk (after formatting). In fact, in many systems these parameters are never changed during the life of the system.

- 4. The requirement to support a software interface that is independent of the type of disk attached to the system. In this case, a system generated ("logical") disk address (drive, head, cylinder, and sector numbers) must be mapped into a physical floppy disk address. For example, to switch between single-and dual-sided disks, it may be easier and more cost-effective for the software to treat the dual-sided disk as containing twice as many sectors per track (52) rather than as having two sides. With this technique, accesses to sectors 1 through 26 are mapped onto head 0 while accesses to sectors 27 through 52 are mapped onto head 1.
- 5. The necessity of supporting a bad track map. Since bad tracks depend on the disk media, the bad track mapping varies from disk to disk. In general, the system and application software should not be concerned with calculating bad track parameters. Instead, these software modules should refer to cylinders logically (0 through 76). The logical interface level procedures must map these cylinders into physical cylinder positions in order to avoid the bad tracks.

The key to logical interface software design is the mapping of the "logical disk interface" (as seen by the application software) into the "physical disk interface" (as implemented by the floppy disk drivers). This logical to physical mapping is tightly coupled to system software design and the mapping serves to isolate both applications and system software from the peculiarities of the FDC device. Typical logical interface procedures are described in Table 1.

### The File System Interface Level

The file system typically comprises the highest level of disk interface software used by application programs. The file system is designed to treat the disk as a collection of named data areas (known as files). These files are cataloged in the disk directory. File system interface software permits the creation of new files and the deletion of existing files under software control. When a file is created, its name and disk address are entered into the directory; when a file is deleted, its name is removed from the directory. Application software requests the use of a file by executing an OPEN function. Once opened, a file is normally reserved for use by the requesting program or task and the file cannot be reopened by other tasks. When a task no longer needs to use an open file, the task closes the file, releasing it for use by other tasks.

Most file systems also support a set of file attributes that can be specified for each file. File attributes may be used to protect files (e.g., the WRITE PROTECT attribute ensures that an existing file cannot accidentally be overwritten) and to supply system configuration information (e.g., a FORMAT attribute may specify that a file should automatically be created on a new disk when the disk is formatted).

At the file system interface level, application programs need not be explicitly aware of disk storage allocation techniques, block sizes, or file coding strategies. Only a "file name" must be presented in order to open, read or write, and subsequently close a file. Typical file system functions are listed in Table 2.

2-175 AFN-01949A

Table 1: Examples of Logical Interface Procedures

Name Language	cylinder, and sector numbers) must be mapped into a principle floopy disk address noitqirosed to switch between
FORMAT DISK	
RECALIBRATE	
SEEK STEWNICS REPORT NAME OF STEWNICS AND ST	Moves the disk read/write head to a specified logical cylinder. The logical and physical cylinder numbers may be different if bad track mapping is used.
READ STATUS	Indicates the status of the floppy disk drive and media. One important use of this procedure is to determine whether a floppy disk is dual-sided.
READ SECTOR SECTOR	Reads one or more complete sectors starting at a specified disk address (drive, head, cylinder, and sector).
WRITE SECTOR	Writes one or more complete sectors starting at a specified disk address (drive, head, cylinder, and sector).

The file system typically comprises the highest level of disk interface software used by application programs. The file system is designed to treat the disk as a collection of named data areas (known as files). These files are cataloged in the disk directory. File system interface software permits the creation of new files and the deletion of existing files under software control. When a file is created, its name and disk address are entered into the directory; when a file is deleted, its name is removed from the directory. Application software requests the use of a file by executing an OPHM function. Once opened, a file is normally reserved for use by the requesting program or task and the file cannot be received by other tasks. When a task no longer needs to use an open file, the task closes the file, releasing it for use by other tasks.

Most file systems also support a set of file attributes that can be specified for each file. File attributes may be used to protect files (e.g., the WRITE PROTECT attribute ensures that an existing file cannot accidentally be overwartten) and to supply system configuration information (e.g., a FORMAT attribute ensures that an existing file cannot accidentally be overwarted 

At the file mystem interface level, application programs need not be explicitly aware of disk storage allocation techniques, block sizes, or file coding strategies. Only a "file name" must be presented in order to open, read or write, and subsequently close a file. Typical file system functions are listed in

Read a file of executable code into memory.	CAOL
Initialize a disk by formatting the media and establishing the directory file, the bit map file, and other system files.	IMITDISK

### permand of me 2. Disk I/O Techniques

One of the most important software aspects of disk interfacing is the fixed sector size. (Sector sizes are fixed when the disk is formatted.) Individual bytes of disk storage cannot be read/written; instead, complete sectors must be transferred between the floppy disk and system memory.

Selection of the appropriate sector size involves a tradeoff between memory size, disk storage efficiency, and disk transfer efficiency. Basically, the following factors must be weighed:

- 1. Memory size. The larger the sector size, the larger the memory area that must be reserved for use during disk I/O transfers. For example, a lK byte disk sector size requires that at least one lK memory block be reserved for disk I/O.
- 2. Disk Storage efficiency. Both very large and very small sectors can waste disk storage space as follows. In disk file systems, space must be allocated somewhere on the disk to link the sectors of each file together. If most files are composed of many small sectors, a large amount of linkage overhead information is required. At the other extreme, when most files are smaller than a single disk sector, a large amount of space is wasted at the end of each sector.
- Disk transfer efficiency. A file composed of a few large sectors can be transferred to/from memory more efficiently (faster and with less overhead) than a file composed of many small sectors.

Balancing these considerations requires knowledge of the intended system applications. Typically, for general purpose systems, sector sizes from 128 bytes to 1K bytes are used. For compatibility between single-density and double-density recording with the 8272 floppy disk controller, 256 byte sectors or 512 byte sectors are most useful.

# FDC Data Transfer Interface bed smeleys east at .loog relied a more bedacolls

Three distinct software interface techniques may be used to interface system memory to the FDC device during sector data transfers:

- DMA In a DMA implementation, the software is only required to set up the DMA controller memory address and transfer count, and to initiate the data transfer. The DMA controller hardware handshakes with the processor/system bus in order to perform each data transfer.
- 2. Interrupt Driven The FDC generates an interrupt when a data byte is ready to be transferred to memory, or when a data byte is needed from memory. It is the software's responsibility to perform appropriate memory reads/writes in order to transfer data from/to the FDC upon receipt of the interrupt.
- 3. Polling Software responsibilities in the polling mode are identical to the responsibilities in the interrupt driven mode. The polling mode, however, is used when interrupt service overhead (context switching) is too large to support the disk data

rate. In this mode, the software determines when to transfer data by continually polling a data request status flag in the notes be FDC status register. I wait to stoogs elevates transfer and add to end to

The DMA mode has the advantage of permitting the processor to continue executing instructions while a disk transfer is in progress. (This capability is especially useful in multiprogramming environments when the operating system is designed to permit other tasks to execute while a program is waiting for I/O.) Modes 2 and 3 are often combined and described as non-DMA operating modes. Non-DMA modes have the advantage of significantly lower system cost, but are often performance limited for double-density systems (where data bytes must be transferred to/from the FDC every 16 microseconds).

For example, a 1% byte disk sector size requires that at least

### Overlapped Operations

Some FDC devices support simultaneous disk operations on more than one disk drive. Normally seek and recalibrate operations can be overlapped in this manner. Since seek operations on most floppy drives are extremely slow, this mode of operation can often be used by the system software to reduce overall disk access times.

#### Buffers

The buffer concept is an extremely important element in advanced disk I/O strategies. A buffer is nothing more than a memory area containing the same amount of data as a disk sector contains. Generally, when an application program requests data from a disk, the system software allocates a buffer (memory area) and transfers the data from the appropriate disk sector into the buffer. The address of the buffer is then returned to the application software. In the same manner, after the application program has filled a buffer for output, the buffer address is passed to the system software, which writes data from the buffer into a disk sector. In multitasking systems, multiple buffers may be allocated from a buffer pool. In these systems, the disk controller is often requested to read ahead and fill additional data buffers while the application software is processing a previous buffer. Using this technique, system software attempts to fill buffers before they are needed by the application programs, thereby eliminating program waits during I/O transfers. Figure 1 illustrates the use of multiple buffers in a ring configuration.

to set up the DMA controller memory address and transfer count, and to initiate the data transfer. The DMA controller hardware handshakes with the processor/system bus in order to perform each data transfer.

Interrupt Driven - The FDC generates an interrupt when a data byte is ready to be transferred to memory, or when a data byte is needed from memory. It is the software's responsibility to perform appropriate memory reads/writes in order to transfer data from/to the FDC upon receipt of the interrupt.

Polling - Software responsibilities in the polling mode are identical to the responsibilities in the interrupt driven mode. The polling mode, however, is used when interrupt service overhead (context switching) is too large to support the disk data

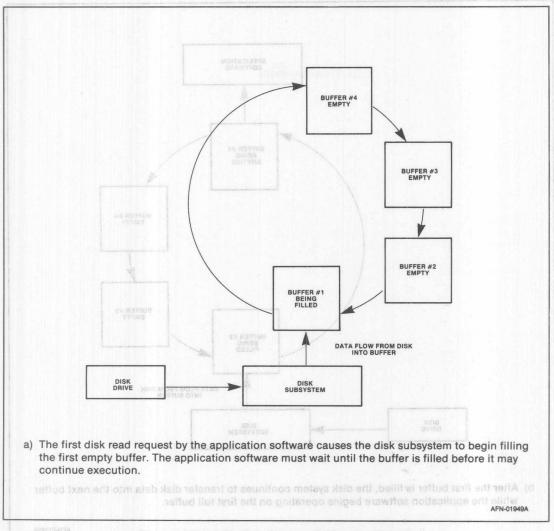

Figure 1. Using Multiple Memory Buffers for Disk I/O

2-181

AFN-01949A

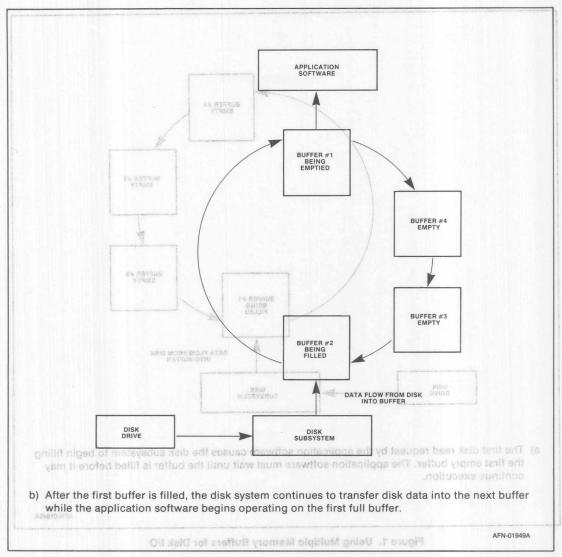

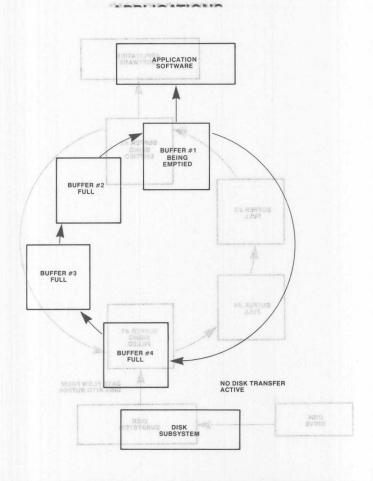

Figure 1. Using Multiple Memory Buffers for Disk I/O (Continued)

c) When all empty buffers have been filled, disk activity is stopped until the application software sector read to reflet the buffer. This strategy attempt, each to minimize data transfer delays. If maintaining a sufficient number of full data buffers in order to minimize data transfer delays. If ARM-1014 at a life of the application software requests it, no disk transfer delays.

Interface Registers

### 3. THE 8272 FLOPPY DISK CONTROLLER

The 8272 is a single-chip LSI Floppy Disk Controller (FDC) that implements both single- and double-density floppy disk storage subsystems (with up to four dual-sided disk drives per FDC). The 8272 supports the IBM 3740 single-density recording format (FM) and the IBM System 34 double-density recording format (MFM). The 8272 accepts and executes high-level disk commands such as format track, seek, read sector, and write sector. All data synchronization and error checking is automatically performed by the FDC to ensure reliable data storage and subsequent retrieval. The 8272 interfaces to microprocessor systems with or without Direct Memory Access (DMA) capabilities and also interfaces to a large number of commercially available floppy disk drives.

## status registera (STO, STI, ST2, and ST3). These registers are only available fluring the result phase of a command

The 8272 executes fifteen high-level disk interface commands:

	STATE OF THE PARTY
Specify	Write Data
Sense Drive Status	Write Deleted Data goo cycs ont stall A e
Sense Interrupt Status	
Seek regult status regis ses	
Recalibrate	Scan Equal elder ni berstraulli ers (ETR-
Format Track	Scan High or Equal
Read Data - nation avoid and	Scan Low or Equal and do idw atab to setted
Read Deleted Data	se, and are read out of the 8272 in the resu

In addition to the Main Status Register, the FDC contains four additional

Each command is initiated by a multi-byte transfer from the driver software to the FDC (the transferred bytes contain command and parameter information).

After complete command specification, the FDC automatically executes the command. The command result data (after execution of the command) may require a multi-byte transfer of status information back to the driver. It is convenient to consider each FDC command as consisting of the following three phases:

Command Phase:	The driver transfers to the FDC all the information
	required to perform a particular disk operation. The
sfully complete	0070
until all seven	DECEMBER and Callering the second of the second
	phase (if any) of a previous command.

Execution Phase: The FDC performs the operation as instructed. The execution phase is entered immediately after the last command parameter is written to the FDC in the preceding command phase. The execution phase normally ends when the last data byte is transferred to/from the disk or when an error occurs.

Result Phase: After completion of the disk operation, status and other housekeeping information are made available to the driver software. After this information is read, the FDC reenters the command phase and is ready to accept another command.

2-185

## 

To support information transfer between the FDC and the system software, the 8272 contains two 8-bit registers: the Main Status Register and the Data Register. The Main Status Register (read only) contains FDC status information and may be accessed at any time. The Main Status Register (Table 3) provides the system processor with the status of each disk drive, the status of the FDC, and the status of the processor interface. The Data Register (read/write) stores data, commands, parameters, and disk drive status information. The Data Register is used to program the FDC during the command phase and to obtain result information after completion of FDC operations.

In addition to the Main Status Register, the FDC contains four additional status registers (ST0, ST1, ST2, and ST3). These registers are only available during the result phase of a command.

### Command/Result Phases

Table 4 lists the 8272 command set. For each of the fifteen commands, command and result phase data transfers are listed. A list of abbreviations used in the table is given in Table 5, and the contents of the result status registers (STO-ST3) are illustrated in Table 6.

The bytes of data which are sent to the 8272 by the drivers during the command phase, and are read out of the 8272 in the result phase, must occur in the order shown in Table 4. That is, the command code must be sent first and the other bytes sent in the prescribed sequence. All bytes of the command and result phases must be read/written as described. After the last byte of data in the command phase is sent to the 8272 the execution phase automatically starts. In a similar fashion, when the last byte of data is read from the 8272 in the result phase, the result phase is automatically ended and the 8272 reenters the command phase.

It is important to note that during the result phase all bytes shown in Table 4 must be read. The Read Data command, for example, has seven bytes of data in the result phase. All seven bytes must be read in order to successfully complete the Read Data command. The 8272 will not accept a new command until all seven bytes have been read. The number of command and result bytes varies from command-to-command.

In order to read data from, or write data to, the Data Register during the command and result phases, the software driver must examine the Main Status Register to determine if the Data Register is available. The DIO (bit 6) and RQM (bit 7) flags in the Main Status Register must be low and high, respectively, before each byte of the command word may be written into the 8272. Many of the commands require multiple bytes, and as a result, the Main Status Register must be read prior to each byte transfer to the 8272. To read status bytes during the result phase, DIO and RQM in the Main Status Register must both be high. Note, checking the Main Status Register in this manner before each byte transfer to/from the 8272 is required only in the command and result phases, and is NOT required during the execution phase.

	080 1 0 0 Drive 2 W
tus Information out the FOD	to 1 1 Drive 3 Blood Engineer 1 0 F r M2 M464 TM W Disministra
Transport Control of C	Special Sector Size. During the execution of disk read/write commands, this parameter is used to temporarily alter the effective disk sector size. By setting N to zero, DTL may be used to specify a sector size from 1 to 256 bytes in length. If the actual sector (on the disk) is larger than DTL specifies, the remainder of the actual sector is not passed to the system during read commands; during write commands, the remainder of the actual sector is written with all-zeroes bytes. DTL should be set to FF hexadecimal when N is not zero.
EOT	End of Track. The final sector number of the current track.
GPL	Gap Length. The gap 3 size. (Gap 3 is the space between sectors.)
н	Head Address. Selected head: 0 or 1 (disk side 0 or 1, respectively) as encoded in the sector ID field.
HLT	Head Load Time. Defines the time interval that the FDC waits after loading the head before initiating a read or write operation. Programmable from 2 to 254 milliseconds (in increments of 2 ms).
нит	Head Unload Time. Defines the time interval from the end of the execution phase (of a read or write command) until the head is unloaded. Programmable from 16 to 240 milliseconds (in increments of 16 ms).
MFM	MFM/FM Mode Selector. Selects MFM double-density recording mode when high, FM single-density mode when low.
MT	Multi-Track Selector. When set, this flag selects the multi-track operating mode. In this mode (used only with dual-sided disks), the FDC treats a complete cylinder (under both read/write head 0 and read/write head 1) as a single track. The FDC operates as if this expanded track started at the first sector under head 0 and ended at the last sector under head 1. With this flag set (high), a multi-sector read operation will automatically continue to the first sector under head 1 when the FDC finishes operating on the last sector under head 0.

ND	Non-DMA Mode Flag. When set (1), this flag indicates that the FDC
IND	is to operate in the non-DMA mode. In this mode, the processor
	participates in each data transfer (by means of an interrupt or by
	polling the RQM flag in the Main Status Register). When reset (0),
	the FDC interfaces to a DMA controller. 30
	REM
R	Sector Address. Specifies the sector number to be read or written. In
	multi-sector transfers, this parameter specifies the sector number of
	the first sector to be read or written.
agy br	00 - Wormen termination of command. The specified comman
SC	Number of Sectors per Track. Specifies the number of sectors per track
	to be initialized by the Format Track command.
0.60	01 - Abnormal termination of command. Command execution
SK	Skip Flag. When this flag is set, sectors containing deleted data
	address marks will automatically be skipped during the execution of
e execut	· Andrew Committee Committ
	containing a data address mark will automatically be skipped during
e disk	the execution of a multi-sector Read Deleted Data command.
	drive ready signal changed state.
SRT	Step Rate Interval. Defines the time interval between step pulses
ed the	issued by the FDC (track-to-track access time). Programmable from
end	1 to 16 milliseconds (in increments of 1 ms).
	correct cylinder.
STO	Status Register 0-3. Registers within the FDC that store status infor-
STL	mation after a command has been executed. This status information is
ST2	available to the processor during the Result Phase after command exe-
ST3	cution. These registers may only be read after a command has been
	executed (in the exact order shown in Table 4 for each command).
	These registers should not be confused with the Main Status Register.
i herem	NR Not Ready Error, This flag is set if a read or write or
	Scan Sector Increment. During Scan operations, this parameter is
Prenada	added to the current sector number in order to determine the next
	sector to be scanned.

Status Recister 1

TIE NESKU	SYMBOL	DESCRIPTION
		End of Track Error. This flag is set if the FDC attempts to access a sector beyond the final sector of the track.
		Undefined
		Data Error. Set when the FDC detects a CRC error in either the the ID field or the data field of a sector.
b		Overrum Error. Set (during data transfers) if the FDC does not receive DMA or processor service within the specified time interval.

DSI,DSO Drive Select. The number of the drive selected at the time of

2-191 AFN-01949A

the interrupt.

## Execution Phase isub tol abom word-littlem a ni aistage of banglash cala al DOW and

All data transfers to (or from) the floppy drive occur during the execution phase. The 8272 has two primary modes of operation for data transfers (selected by the specify command):

- 1) DMA mode
- 2) non-DMA mode

In the DMA mode, execution phase data transfers are handled by the DMA controller hardware (invisible to the driver software). The driver software, however, must set all appropriate DMA controller registers prior to the beginning of the disk operation. An interrupt is generated by the 8272 after the last data transfer, indicating the completion of the execution phase, and the beginning of the result phase.

In the non-DMA mode, transfer requests are indicated by generation of an interrupt and by activation of the RQM flag (bit 7 in the Main Status Register). The interrupt signal can be used for interrupt-driven systems and RQM can be used for polled systems. The driver software must respond to the transfer request by reading data from, or writing data to, the FDC. After completing the last transfer, the 8272 generates an interrupt to indicate the beginning of the result phase. In the non-DMA mode, the processor must activate the "terminal count" (TC) signal to the FDC (normally by means of an I/O port) after the transfer request for the last data byte has been received (by the driver) and before the appropriate data byte has been read from (or written to) the FDC.

In either mode of operation (DMA or non-DMA), the execution phase ends when a "terminal count" signal is sensed by the FDC, when the last sector on a track (the EOT parameter - Table 4) has been read or written, or when an error of bileval occurs.

If an invalid (undefined) command is sent to the FDC, the FDC will terminate the command. No interrupt is generated by the 8272 during this condition.

#### Multi-sector and Multi-track Transfers also and al (MOA bas Old) V 31d bas 3 118

During disk read/write transfers (Read Data, Write Data, Read Deleted Data, and Write Deleted Data), the FDC will continue to transfer data from sequential sectors until the TC input is sensed. In the DMA mode, the TC input is normally set by the DMA controller. In the non-DMA mode, the processor directly controls the FDC TC input as previously described. Once the TC input is received, the FDC stops requesting data transfers (from the system software or DMA controller). The FDC, however, continues to read data from, or write data to, the floppy disk until the end of the current disk sector. During a disk read operation, the data read from the disk (after reception of the TC input) is discarded, but the data CRC is checked for errors; during a disk write operation, the remainder of the sector is filled with all-zero bytes.

If the TC signal is not received before the last byte of the current sector has been transferred to/from the system, the FDC increments the sector number by one and initiates a read or write command for this new disk sector.

The FDC is also designed to operate in a multi-track mode for dual-sided disks. In the multi-track mode (specified by means of the MT flag in the command byte - Table 4) the FDC will automatically increment the head address of IfA (from 0 to 1) when the last sector (on the track under head 0) has been read or written. Reading or writing is then continued on the first sector (sector 1) of head 1.

### Drive Status Polling

After the power-on reset, the 8272 automatically enters a drive status of AMO and polling mode. If a change in drive status is detected (all drives are assumed to be "not ready" at power-on), an interrupt is generated. The 8272 continues this status polling between command executions (and between step pulses in the Seek command). In this manner, the 8272 automatically notifies the system software whenever a floppy disk is inserted, removed, or changed by the operator.

#### In the non-DMA mode, transfer requests are indicated by generation and in

During the command phase, the Main Status Register must be polled by the driver software before each byte is written into the Data Register. The DIO (bit 6) and or RQM (bit 7) flags in the Main Status Register must be low and high, respectively, before each byte of the command may be written into the 8272. The beginning of the execution phase for any of these commands will cause DIO to be set high and RQM to be set low.

Operation of the FDC commands is described in detail in Application Note AP-116, and "An Intelligent Data Base System Using the 8272."

### Invalid Commands a whole to written, or when a Table 4) has been read or written, or when a Table 4)

If an invalid (undefined) command is sent to the FDC, the FDC will terminate the command. No interrupt is generated by the 8272 during this condition.

Bit 6 and bit 7 (DIO and RQM) in the Main Status Register are both set indicating to the processor that the 8272 is in the result phase and the contents of Status Register 0 must be read. When the processor reads Status Register 0 it will find an 80H code indicating that an invalid command was received.

The driver software in Appendix B checks each requested command and will not assume an invalid command to the 8272.

A Sense Interrupt Status command must be sent after a Seek or Recalibrate per a command interrupt; otherwise the FDC will consider the next command to be an invalid command. Also, when the last "hidden" interrupt has been serviced, further a sense Interrupt Status commands will result in invalid command codes.

been transferred to/from the system, the FDC increments the sector number by one

2-196 AFN-01949A

## 4. 8272 Physical Interface Software

PL/M software driver listings for the 8272 FDC are contained in Appendix A. These drivers have been designed to operate in a DMA environment (as described in Application Note AP-116, "An Intelligent Data Base System Using the 8272"). In the following paragraphs, each driver procedure is described. (A description of the driver data base variables is given in Table 7.) In addition, the modifications necessary to reconfigure the drivers for operation in a polled environment are discussed.

#### INITIALIZE\$DRIVERS dalog to years Isnaedal na

This initialization procedure must be called before any FDC operations are attempted. This module initializes the DRIVE\$READY, DRIVE\$STATUS\$CHANGE, OPERATION\$IN\$PROGRESS, and OPERATION\$COMPLETE arrays as well as the GINESON COMPLETE arrays as well as the GINESON COMPLETE ARRAY OF C

## EXECUTE\$DOCB TO and yd beau yaxra lannedni nA

This procedure contains the main 8272 driver control software and handles the execution of a complete FDC command. EXECUTE\$DOCB is called with two parameters: a) a pointer to a disk operation control block and b) a pointer to a result status byte. The format of the disk operation control block is illustrated in Figure 2 and the result status codes are described in Table 8.

Before starting the command phase for the specified disk operation, the command is checked for validity and to determine whether the FDC is busy. (For an overlapped operation, if the FDC BUSY flag is set — in the Main Status Register — the command cannot be started; non-overlapped operations cannot be started if the FDC BUSY flag is set, if any drive is in the process of seeking/recalibrating, or if an operation is currently in progress on the specified drive.)

After these checks are made, interrupts are disabled in order to set the OPERATION\$IN\$PROGRESS flag, reset the OPERATION\$COMPLETE flag, load a pointer to the current operation control block into the OPERATION\$DOCB\$PTR array and set GLOBAL\$DRIVE\$NO (if a non-overlapped operation is to be started).

At this point, parameters from the operation control block are output to the DMA controller and the FDC command phase is initiated. After completion of the command phase, a test is made to determine the type of result phase required for the current operation. If no result phase is needed, control is immediately returned to the calling program. If an immediate result phase is required, the result bytes are input from the FDC. Otherwise, the CPU waits until the OPERATION\$COMPLETE flag is set (by the interrupt service procedure).

Finally, if an error is detected in the result status code (from the FDC), an FDC operation error is reported to the calling program.

#### FDCINT

This procedure performs all interrupt processing for the 8272 interface drivers. Basically, two types of interrupts are generated by the 8272: (a) an interrupt that signals the end of a command execution phase and the beginning of the result phase and (b) an interrupt that signals the completion of an overlapped operation or the occurrence of an unexpected event (e.g., change in the drive "ready" status).

An interrupt of type (a) is indicated when the FDC BUSY flag is set (in the Main Status Register). When a type (a) interrupt is sensed, the result bytes a single are read from the 8272 and placed in the result portion of the disk operation control block, the appropriate OPERATION\$COMPLETE flag is set, and the OPERATION\$IN\$PROGRESS flag is reset.

When an interrupt of type (b) is indicated (FDC not busy), a sense interrupt status command is issued (to the FDC). The upper two bits of the result status usual register (Status Register Zero - STO) are used to determine the cause of the interrupt. The following four cases are possible:

- 1) Operation Complete. An overlapped operation is complete. The GOL of sham all drive number is found in the lower two bits of STO. The STO data and of sham is transferred to the active operation control block, the OPERATION\$COMPLETE flag is set, and the OPERATION\$IN\$PROGRESS flag is reset.
- 2) Abnormal Termination. A disk operation has abnormally terminated. The drive number is found in the lower two bits of STO. The STO data is transferred to the active control block, the OPERATION\$COM- and also PLETE flag is set, and the OPERATION\$IN\$PROGRESS flag is reset.
- 4) Drive Status Change. A change has occurred in the "ready" status of a disk drive. The drive number is found in the lower two bits of STO. The DRIVE\$READY flag for this disk drive is set to the new drive "ready" status and the DRIVE\$STATUS\$CHANGE flag for the drive is also set. In addition, if a command is currently in progress, the STO data is transferred to the active control block, making the OPERATION\$COMPLETE flag is set, and the OPERATION\$IN\$PROGRESS and flag is reset.

After processing a type (b) interrupt, additional sense interrupt status commands must be issued and processed until an "invalid command" result is returned from the FDC. This action guarantees that all "hidden" interrupts are serviced.

In addition to the major driver procedures described above, a number of support procedures are required. These support routines are briefly described in the equal following paragraphs.

2-201 AFN-01949A

#### OUTPUT\$CONTROLS\$TO\$DMA

This procedure outputs the DMA mode, the DMA address, and the DMA word count to the 8237 DMA controller. In addition, the upper four bits of the 20-bit DMA address are output to the address extension latch. Finally, the disk DMA channel is started.

#### OUTPUT\$COMMAND\$TO\$FDC

This software module outputs a complete disk command to the 8272 FDC. The pass a self-number of required command/parameter bytes is found in the COMMAND\$LENGTH table. The appropriate bytes are output one at a time (by calls to OUTPUT\$BYTE\$TO\$FDC) from the command portion of the disk operation control block.

When an interrupt of type (b) is indicated (FDC not busy), a sense interrupt

4) Drive Status Change. A change has occurred in the "ready" status

## INPUT\$RESULT\$FROM\$FDC to afid own ragge edt . (DOT and of) beusal al bosomoro autain

This procedure is used to read result phase status information from the disk controller. At most, seven bytes are read. In order to read each byte, a call is made to INPUT\$BYTE\$FROM\$FDC. When the last byte has been read, a check is made to insure that the FDC is no longer busy.

#### OUTPUT\$BYTE\$TO\$FDC

This software is used to output a single command/parameter byte to the FDC. A This procedure waits until the FDC is ready for a command byte and then outputs the byte to the FDC data port.

#### 3) Invalid Command. - The execution of an invalid command invalid invalid Command.

This procedure inputs a single result byte from the FDC. The software waits until the FDC is ready to transfer a result byte and then reads the byte from the FDC data port.

## FDC\$READY\$FOR\$COMMAND a stevint dails sidt tot gell YGAGASXVIRG edt. OTS to

This procedure assures that the FDC is ready to accept a command/parameter byte by performing the following three steps. First, a small time interval (more than 20 microseconds) is inserted to assure that the RQM flag has time to become valid (after the last byte transfer). Second, the master request flag (RQM) is polled until it is activated by the FDC. Finally, the DIO flag is checked to ensure that it is properly set for FDC input (from the processor).

#### FDC\$READY\$FOR\$RESULT

The operation of this procedure is similar to the FDC\$READY\$FOR\$COMMAND with the following exception. If the FDC BUSY flag (in the Main Status Register) is not set, the result phase is complete and no more data is available from the FDC. Otherwise, the procedure waits for the RQM flag and checks the DIO flag for FDC output (to the processor).

2-202 AFN-01949A

## OPERATION\$CLEAN\$UP

This procedure is called after the execution of a disk operation that has no result phase. OPERATION\$CLEAN\$UP resets the OPERATION\$IN\$PROGRESS flag and the good GLOBAL\$DRIVE\$NO variable if appropriate. This procedure is also called to clean up after some disk operation errors.

word 1 to be to expend the manual man

To operate in the polling mode, the following modifications should be made to the previous routines:

- 1. The OUTPUT\$CONTROLS\$TO\$DMA routine should be deleted. If add of relation and an engage
- 2. In EXECUTE\$DOCB, immediately prior to WAIT\$FOR\$OP\$COMPLETE, a polling loop should be inserted into the code. The loop should test the RQM flag (in the Main Status Register). When RQM is set, a data byte should be written to, or read from, the 8272. The buffer address may be computed from the base address contained in DOCB.DMA\$ADDR and DOCB.DMA\$ADDR\$EXT. After the correct number of bytes have been transferred, an operation complete interrupt will be issued by the FDC. During data transfer in the non-DMA mode, the NON-DMA MODE flag (bit 5 of the Main Status Register) will be set. This flag will remain set for the complete execution phase. When the transfer is finished, the NON-DMA MODE flag is reset and the result phase interrupt is issued by the FDC.

This procedure causes the floppy disk read/write head to retract to track 0. The RECALIBRATE procedure requires only one parameter — the drive number on which the recalibrate operation is to be performed. This procedure builds a disk operation control block (RECALIBRATE;DOCE) and passes the control block to the FDC driver for execution.

This procedure causes the disk read/write head (on the selected drive) to move to the desired cylinder position. The SEEK procedure is called with three perameters: drive number (DRV), head/side number (HD), and cylinder number (CFE). This software module builds a disk operation control block (SEEKSDOCB) that is executed by the FDC driver.

TAMEUT

The FORMAT procedure is designed to initialize a complete floppy disk so that sectors can subsequently be read and written by system and application programs. Three parameters must be supplied to this procedure: the drive number (DEV), the recording density (DEWS), and the interleave factor (INTLVE). The FORMAT procedure generates a data block (FMTELK) and a disk operation control block (FORMATSDOCE) for each track on the floppy disk (normally 77).

2-203 AFN-01949A

#### 5. 8272 Logical Interface Software

Appendix B of this Application Note contains a PL/M listing of an exerciser program for the 8272 drivers. This program illustrates the design of logical interface level procedures to specify disk parameters, recalibrate a drive, seek to a cylinder, format a disk, read data, and write data.

The exerciser program is written to operate a standard single-sided 8" floppy disk drive in either the single- or double-density recording mode. Only the eight parameters listed in Table 9 must be specified. All other parameters are derived from these 8 basic variables.

Each of these logical interface procedures is described in the following paragraphs (refer to the listing in Appendix B).

 In EXECUTESDOCE, immediately prior to WAITSTORSOPSCOMPLETE, a polling loop should be inserted into the code. The loop should

#### SPECIFY

This procedure sets the FDC signal timing so that the FDC will interface correctly to the attached disk drive. The SPECIFY procedure requires four parameters, the step rate (SRT), head load time (HLT), head unload time (HUT), and the non-DMA mode flag (ND). This procedure builds a disk operation control block (SPECIFY\$DOCB) and passes the control block to the FDC driver module (EXECUTE\$DOCB) for execution. (Note carefully the computation required to transform the step rate (SRT) into the correct 8272 parameter byte.)

#### RECALIBRATE

This procedure causes the floppy disk read/write head to retract to track 0. The RECALIBRATE procedure requires only one parameter — the drive number on which the recalibrate operation is to be performed. This procedure builds a disk operation control block (RECALIBRATE\$DOCB) and passes the control block to the FDC driver for execution.

#### SEEK

This procedure causes the disk read/write head (on the selected drive) to move to the desired cylinder position. The SEEK procedure is called with three parameters: drive number (DRV), head/side number (HD), and cylinder number (CYL). This software module builds a disk operation control block (SEEK\$DOCB) that is executed by the FDC driver.

#### FORMAT

The FORMAT procedure is designed to initialize a complete floppy disk so that sectors can subsequently be read and written by system and application programs. Three parameters must be supplied to this procedure: the drive number (DRV), the recording density (DENS), and the interleave factor (INTLVE). The FORMAT procedure generates a data block (FMTBLK) and a disk operation control block (FORMAT\$DOCB) for each track on the floppy disk (normally 77).

Table 9: Basic Disk Parameters

Name (1939manag 1)	Description Laborated and the property of the
DENSITY	The recording mode (FM or MFM).
FILLER\$BYTE BUSENESS TO L	The data byte to be written in all sectors during formatting.
TRACKS\$PER\$DISK	The number of cylinders on the floppy disk.
BYTES\$PER\$SECTOR	The number of bytes in each disk sector. The exerciser accepts 128, 256, and 512 in FM mode, and 256, 512, and 1024 in MFM mode.
INTERLEAVE	The sector interleave factor for each disk track.
STEP\$RATE	The disk drive step rate (1-16 milliseconds).
HEAD\$LOAD\$TIME	The disk drive head load time (2-254 milliseconds).
HEAD\$UNLOAD\$TIME	The head unload time (16-240 milliseconds).

em operator. This error message lists the drive number, type of operation, and failure status (from the PDC). It is the operator's responsibility to take dditional action as required.

The format data block specifies the four sector ID field parameters (cylinder, head, sector, and bytes per sector) for each sector on the track. The sector numbers need not be sequential; the interleave factor (INTLVE parameter) is used to compute the logical to physical sector mapping.

After both the format data block and the operation control block are generated for a given cylinder, control is passed to the 8272 drivers for execution.

After the format operation is complete, a SEEK to the next cylinder is performed, a new format table is generated, and another track formatting operation is executed by the drivers. This track formatting continues until all tracks on the diskette are formatted.

In some systems, bad tracks must also be specified when a disk is formatted. For these systems, the existing FORMAT procedure should be modified to format bad tracks with a cylinder number of OFFH.

The sector interleave factor for each disk track

#### WRITE

The WRITE procedure transfers a complete sector of data to the disk drive. Five parameters must be supplied to this software module: the drive number (DRV), the cylinder number (CYL), the head/side number (HD), the sector number (SEC) and the recording density (DENS). This procedure generates a disk operation control block (WRITE\$DOCB) from these parameters and passes the control block to the 8272 driver for execution. When control returns to the calling program, the data has been transferred to disk.

#### READ

This procedure is identical to the WRITE procedure except the direction of data transfer is reversed. The READ procedure transfers a sector of data from the floppy disk to system memory.

#### Coping With Errors

In actual practice all logical disk interface routines would contain error processing mechanisms. (Errors have been ignored for the sake of simplicity in the exerciser programs listed in Appendix B.) A typical error recovery technique consists of a two-stage procedure. First, when an error is detected, a recalibrate operation is performed followed by a retry of the failed operation. This procedure forces the drive to seek directly to the requested cylinder (low-ering the probability of a seek error) and attempts to perform the requested operation an additional time. Soft (temporary) errors caused by mechanical or electrical interference do not normally recur during the retry operation; hard errors (caused by media or drive failures), on the other hand, will continue to occur during retry operations. If, after a number of retries (approximately 10), the operation continues to fail, an error message is displayed to the system operator. This error message lists the drive number, type of operation, and failure status (from the FDC). It is the operator's responsibility to take additional action as required.

## 6. File Systems

The file system provides the disk I/O interface level most familiar to users of interactive microcomputer and minicomputer systems. In a file system, all data is stored in named disk areas called files. The user and applications programs need not be concerned with the exact location of a file on the disk — the disk file system automatically determines the file location from the file name. Files may be created, read, written, modified, and finally deleted (destroyed) when they are no longer needed. Each floppy disk typically contains a directory that lists all the files existing on the disk. A directory entry for a file contains information such as file name, file size, and the disk address (track and sector) of the beginning of the file.

## File Allocation | ers seman slid file values of value tile names are by a period (.).

File storage is actually allocated on the disk (by the file system) in fixed size areas called blocks. Normally a block is the same size as a disk sector. Files are created by finding and reserving enough unused blocks to contain the data in the file. Two file allocation methods are currently in widespread use. The first method allocates blocks (for a file) from a sequential pool of unused blocks. Thus, a file is always contained in a set of sequential blocks on the disk. Unfortunately, as files are created, updated, and deleted, these free-block pools become fragmented (separated from one another). When this fragmentation occurs, it often becomes impossible for the file system to create a file even though there is a sufficient number of free blocks on the disk. At this point, special programs must be run to "squeeze" or compact the disk, in order to re-create a single contiguous free-block pool.

The second file allocation method uses a more flexible technique in which individual data blocks may be located anywhere on the disk (with no restrictions). With this technique, a file directory entry contains the disk address of a file pointer block rather than the disk address of the first data block of the file. This file pointer block contains pointers (disk addresses) for each data block in the file. For example, the first pointer in the file pointer block contains the track and sector address of the first data block in the file, the second pointer contains the disk address of the second data block, etc.

In practice, pointer blocks are usually the same size as data blocks. Therefore, some files will require multiple pointer blocks. To accommodate this requirement without loss of flexibility, pointer blocks are linked together, that is, each pointer block contains the disk address of the following pointer block. The last pointer block of the file is signalled by an illegal disk address (e.g., track 0, sector 0 or track OFFH, sector OFFH).

#### The Intel File System

The Intel file system (described in detail in the RMX-80 Users Guide) uses the second disk file allocation method (previously discussed). In order to lower the system overhead involved in finding free data blocks, the Intel file system incorporates a free space management data structure known as a bit map. Each disk sector is represented by a single bit in the bit map. If a bit in the bit map is set to 1, the corresponding disk sector has been allocated. A zero in the bit map indicates that the corresponding sector is free. With this technique, the process of allocating or freeing a sector is accomplished by simply altering the bit map.

File names consist of a basic file name (up to six characters) and a file extension (up to three characters). The basic file name and the file extension are separated by a period (.). Examples of valid file names are: DRIV72.OBJ, XX.TMP, and FILE.CS. In addition, four file attributes are supported (see Figure 3 for attribute definitions).

The bit map and the file directory are placed on prespecified disk tracks are sail (reserved for system use) beginning at track zero.

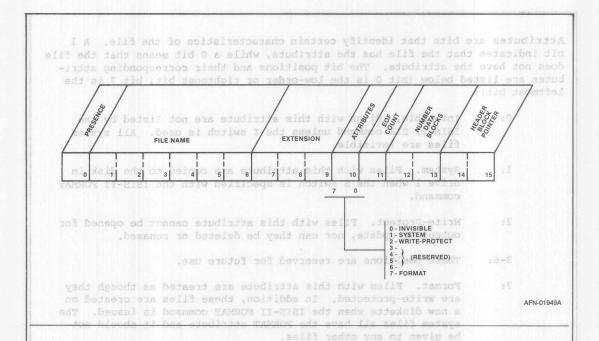

## Disk File System Functions as , bedsbon , bedsete are selfi as , yeldered , walls

Table 2 illustrates the typical functions implemented by a disk file system. As an example, the disk directory function (DIR) lists disk file information on the console display terminal. Figure 3 details the contents of a display entry in the Intel file system. The PL/M procedure outlined in Figure 4 illustrates a disk directory algorithm that displays the file name, the file attributes, and the file size (in blocks) for each file in the directory.

In practice, pointer blocks are usually the same size as data blocks. Therefore some files will require multiple pointer blocks. To accommodate this requirement without loss of flexibility, pointer blocks are linked together, that is, each pointer block contains the disk address of the following pointer block. The last pointer block of the file is signalised by an illegal disk address (e.g., track 0, sector 0 or track OFFE, sector OFTE).

2-208

AFN-01949A

#### Directory Entry

Presence is a flag that can contain one of three values: outsy end at the life of

000H - The file associated with this entry is present on the disk.

07FH - No file is associated with this entry; the content of the rest of the entry is undefined. The first entry with its flag set to 07FH marks the current logical end of the directory and directory searches stop at this entry.

OFFH - The file named in this entry once existed on the disk but is currently deleted. The next file added to the directory will be placed in the first entry marked OFFH. This flag cannot, therefore, be used to (reliably) find a file that has been deleted. A value of OFFH should be thought of as simply marking an open directory entry.

File Name is a string of up to 6 non-blank ASCII characters specifying the name of the file associated with the directory entry. If the file name is shorter than six characters, the remaining bytes contain binary zeros. For example, the name ALPHA would be stored as: 414C50484100H.

**Extension** is a string of up to 3 non-blank ASCII characters that specifies an extension to the file name. Extensions often identify the type of data in the file such as OBJ (object module), or PLM (PL/M source module). As with the file name, unused positions in the extension field are filled with binary zeros.

Figure 3. Intel Directory Entry Format

Attributes are bits that identify certain characteristics of the file. A 1 bit indicates that the file has the attribute, while a 0 bit means that the file does not have the attribute. The bit positions and their corresponding attributes are listed below (bit 0 is the low-order or rightmost bit, bit 7 is the leftmost bit):

- O: Invisible. Files with this attribute are not listed by the ISIS-II DIR command unless the I switch is used. All system files are invisible.
- System. Files with this attribute are copied to the disk in drive 1 when the S switch is specified with the ISIS-II FORMAT command.
- Write-Protect. Files with this attribute cannot be opened for output or update, nor can they be deleted or renamed.
- 3-6: These positions are reserved for future use.
- 7: Format. Files with this attribute are treated as though they are write-protected. In addition, these files are created on a new diskette when the ISIS-II FORMAT command is issued. The system files all have the FORMAT attribute and it should not be given to any other files.

EOF Count contains the number of the last byte in the last data block of the file. If the value of this field is 080H, for example, the last byte in the file is byte number 128 in the last data block (the last block is full).

Number of Data Blocks is an address variable that indicates the number of data blocks currently used by the file. ISIS-II and the RMX/80 Disk File system both maintain a counter called LENGTH that is the current number of bytes in the file. This is calculated as:

((NUMBER OF DATA BLOCKS - 1) x 128 + EOF COUNT.

Header Block Pointer is the address of the file's header block. The high byte of the field is the sector number and the low byte is the track number. The system "finds" a disk file by searching the directory for the name and then using the header block pointer to seek to the beginning of the file.

Figure 3. Intel Directory Entry Format (Continued)

Extension is a string of up to 3 non-blank ASCII characters that specifies an extension to the file name. Extensions often identify the type of data in the file such as OBJ (object module), or PIM (FL/M source module). As with the file name, unused positions in the extension field are filled with binary zeros.

Figure 4. Sample PL/M Directory Procedure

The 8272 constantly polls all drives for changes in the drive ready status. This polling begins immediately following RESET. An interrupt is generated every time the FDC senses a change in the drive ready status. After reset, the FDC assumes that all drives are "not ready". If a drive is ready the FDC assumes that all drives are "not ready".

## 7. Key 8272 Software Interfacing Considerations

This section contains a quick review of **Key** 8272 Software design features and issues. (Most items have been mentioned in other sections of this application note.) Before designing 8272 software drivers, it is advisable that the information in this section be thoroughly understood.

1. Non-DMA Data Transfers and equipment and beard

In systems that operate without a DMA controller (in the polled or interrupt driven mode), the system software is responsible for counting data transfers to/from the 8272 and generating a TC signal to the FDC when the transfer is complete.

2. Processor Command/Result Phase Interface vilgatif psiltsimnol

In the command phase, the driver software must write the exact number of parameters in the exact order shown in Table 5. During the result phase, the driver must read the complete result status. For example, the Format Track command requires six command bytes and presents seven result bytes. The 8272 will not accept a new command until all result bytes are read. Note that the number of command and result bytes varies from command-to-command. Command and result phases cannot be shortened.

During both the command and result phases, the Main Status Register must be read by the driver before each byte of information is read from, or written to, the FDC Data Register. Before each command byte is written, DIO (bit 6) must be low (indicating a data transfer from the processor) and RQM (bit 7) must be high (indicating that the FDC is ready for data). During the result phase, DIO must be high (indicating a data transfer to the processor) and RQM must also be high (indicating that data is ready for the processor).

Note: After the 8272 receives a command byte, the RQM flag may remain set for approximately 16 microseconds (with an 8 MHz clock). The driver should not attempt to read the Main Status Register before this time interval has elapsed; otherwise, the driver may erroneously assume that the FDC is ready to accept the next byte.

4. Samele PL/M Directory Proce

3. Sector Sizes

The 8272 does not support 128 byte sectors in the MFM (double-density) mode.

4. Drive Status Changes

The 8272 constantly polls all drives for changes in the drive ready status. This polling begins immediately following RESET. An interrupt is generated every time the FDC senses a change in the drive ready status. After reset, the FDC assumes that all drives are "not ready". If a drive is ready immediately after reset, the 8272 generates a drive status change interrupt.

#### 5. Seek Commands

The 8272 FDC does not perform implied seeks. Before issuing a data read or write command, the read/write head must be positioned over the correct cylinder by means of an explicit seek command. If the head is not positioned correctly, a cylinder address error is generated.

# (C=1), and so on, until physical track 30 is formatted as log prices formatted as logical 30 (C=30). Physical track 31 is bad and should be formatted as logical

When the processor receives an interrupt from the FDC, the FDC may be reporting one of two distinct events:

- a) The beginning of the result phase of a previously requested read, write, or scan command.
  - b) An asynchronous event such as a seek/recalibrate completion, an attention, an abnormal command termination, or an invalid command.

These two cases are distinguished by the FDC BUSY flag (bit 4) in the Main Status Register. If the FDC BUSY flag is high, the interrupt is of type (a). If the FDC BUSY flag is low, the interrupt was caused by an asynchronous event (b).

A single interrupt from the FDC may signal more than one of the above events.

After receiving an interrupt, the processor must continue to issue Sense
Interrupt Status commands (and service the resulting conditions) until an
invalid command code is received. In this manner, all "hidden" interrupts are
ferreted out and serviced.

#### 7. Skip Flag (SK)

The skip flag is used during the execution of Read Data, Read Deleted Data, Read Track, and various Scan commands. This flag permits the FDC to skip unwanted sectors on a disk track.

When performing a Read Data, Read Track, or Scan command, a high SK flag indicates that the FDC is to skip over (not transfer) any sector containing a deleted data address mark. A low SK flag indicates that the FDC is to terminate the command (after reading all the data in the sector) when a deleted data address mark is encountered.

When performing a Read Deleted Data command, a high SK flag indicates that sectors containing normal data address marks are to be skipped. Note that this is just the opposite situation from that described in the last paragraph. When a data address mark is encountered during a Read Deleted Data command (and the SK flag is low), the FDC terminates the command after reading all the data in the sector.

#### 8. Bad Track Maintenance

The 8272 does not internally maintain bad track information. The maintenance of this information must be performed by system software. As an example of typical bad track operation, assume that a media test determines that track 31 and track 66 of a given floppy disk are bad. When the disk is formatted for use, the system software formats physical track 0 as logical cylinder 0 (C=0 in the command phase parameters), physical track 1 as logical track 1 (C=1), and so on, until physical track 30 is formatted as logical cylinder 30 (C=30). Physcial track 31 is bad and should be formatted as logical cylinder FF (indicating a bad track). Next, physical track 32 is formatted as logical cylinder 31, and so on, until physical track 65 is formatted as logical cylinder 64. Next, bad physical track 66 is formatted as logical cylinder FF (another bad track marker), and physical track 67 is formatted as logical cylinder 65. This formatting continues until the last physical track (77) is formatted as logical cylinder 75. Normally, after this formatting is complete, the bad track information is stored in a prespecified area on the floppy disk (typically in a sector on track 0) so that the system will be able to recreate the bad track information when the disk is removed from the drive and reinserted at some later time.

To illustrate how the system software performs a transfer operation on a disk with bad tracks, assume that the disk drive head is positioned at track 0 and the disk described above is loaded into the drive. If a command to read track 36 is issued by an application program, the system software translates this read command into a seek to physical track 37 (since there is one bad track between 0 and 36, namely 31) followed by a read of logical cylinder 36.

Thus, the cylinder parameter C is set to 37 for the Seek command and 36 for the Read Sector command.

The skip flag is used during the execution of Read Data, Read Deleted Data Read Track, and various Scan commands. This flag permits the FDC to skip unwanted sectors on a disk track.

When performing a Read Data, Read Track, or Scan command, a high SK flag indicates that the FDC is to skip over (not transfer) any sector containing a deleted data address mark. A low SK flag indicates that the FDC is to terminate the command (after reading all the data in the sector) when a deleted data address mark is encountered.

When performing a Read Deleted Data command, a high SK flag indicates that sectors containing normal data address marks are to be skipped. Note that this is just the opposite situation from that described in the last paragraph. When a data address mark is encountered during a Read Deleted Data command (and the SK flag is low), the FDC terminates the command after reading all the data in the sector.

7. Skip Flag (SK)

#### INTRODUCTION

The Intel 8251 is a Universal Synchronous/Asynchronous Receiver/Transmitter (USART) which is capable of operating with a wide variety of serial communication formats. Since many peripheral devices are available with serial interfaces, the 8251 can be used to interface a microcomputer to a broad spectrum of peripherals, as well as to a serial communications channel. The 8251 is part of the MCS-80<sup>TM</sup> Microprocessor Family, and as such it is capable of interfacing to the 8080 system with a minimum of external hardware.

This application note describes the 8251 as a component and then explains its use in sample applications via several examples. A specific use of the 8251 to facilitate communication between two MCS-80 systems is discussed in detail from both the hardware and software viewpoints. The first two sections of this application note describe the 8251 first from a functional standpoint and then on a detailed level. The function of each input and output pin is fully defined. The next section describes the various operating modes and how they can be selected, and finally, a sample design is discussed using the 8251 as a data link between the MCS-80 systems.

## COMMUNICATION FORMATS

Serial communications, either on a data link or with a local peripheral, occurs in one of two basic formats; asynchronous or synchronous. These formats are similar in that they both require framing information to be added to the data to enable proper detection of the character at the receiving end. The major difference between the two formats is that the asynchronous format requires framing information to be added to each character, while the synchronous format adds framing information to blocks of data, or messages. Since the synchronous format is more efficient than the asynchronous format but requires more complex decoding, it is typically found on high-speed data links, while the asynchronous format is used on lower speed lines. The and at she harmond has no rento

The asynchronous format starts with the basic data bits to be transmitted and adds a "START" bit to the front of them and one or more "STOP" bits behind them as they are transmitted. The START bit is a logical zero, or SPACE, and is defined as the positive voltage level by RS-232-C. The STOP bit is a logical one, or MARK, and is defined as the negative voltage level by RS-232-C. In current loop applications current flow normally indicates a MARK and lack of current a SPACE. The START bit tells the receiver to start assembling a character and allows the receiver to synchronize itself with the transmitter. Since this synchronization only

has to last for the duration of the character (the next character will contain a new START bit), this method works quite well assuming a properly designed receiver. One or more STOP bits are added to the end of the character to ensure that the START bit of the next character will cause a transition on the communication line and to give the receiver time to "catch up" with the transmitter if its basic clock happens to be running slightly slower than that of the transmitter. If, on the other hand, the receiver clock happens to be running slightly faster than the transmitter clock, the receiver will perceive gaps between characters but will still correctly decode the data. Because of this tolerance to minor frequency deviations, it is not necessary that the transmitter and receiver clocks be locked to the identical frequency for successful asynchronous communication.

The synchronous format, instead of adding bits to each character, groups characters into records and adds framing characters to the record. The framing characters are generally known as SYN characters and are used by the receiver to determine where the character boundaries are in a string of bits. Since synchronization must be held over a fairly long stream of data, bit synchronization is normally either extracted from the communication channel by the modem or supplied from an external source.

An example of the synchronous and asynchronous formats is shown in Figure 1. The synchronous format shown is fairly typical in that it requires two SYN characters at the start of the message. The asynchronous format, also typical, requires a START bit preceding each character and a single STOP bit following it. In both cases, two 8-bit characters are to be transmitted. In the asynchronous mode 10\*n bits are used to transmit n characters and in the synchronous mode 8N + 16 bits are used. For the example shown the asynchronous mode is actually more efficient, using 20 bits versus 32. To transmit a thousand characters in the asynchronous mode, however, takes 10,000 bits versus 8.016 for the synchronous format mode. For long messages the synchronous format becomes much more efficient than the asynchronous format; the crossover point for the examples shown in Figure 1 is eight characters, for which both formats require 80 bits.

In addition to the differences in format between synchronous and asynchronous communication, there are differences with regards to the type of modems that can be used. Asynchronous modems typically employ FSK (Frequency Shift Keying) techniques which simply generate one audio tone for a MARK and another for a SPACE. The receiving modem detects these tones on the telephone

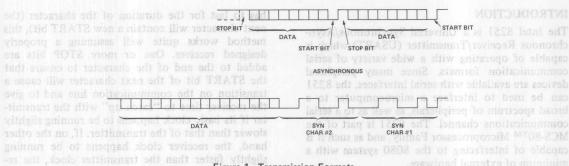

Figure 1. Transmission Formats

line, converts them to logical signals, and presents them to the receiving terminal. Since the modem itself is not concerned with the transmission speed, it can handle baud rates from zero to its maximum speed. Synchronous modems, in contrast to asynchronous modems, supply timing information to the terminal and require data to be presented to them in synchronism with this timing information. Synchronous modems, because of this extra clocking, are only capable of operating at certain preset baud rates. The receiving modem, which has an oscillator running at the same frequency as the transmitting modem, phase locks its clock to that of the transmitter and interprets changes of phase as data.

In some cases it is desirable to operate in a hybrid mode which involves transmitting data with the asynchronous format using a synchronous modem. This occurs when an increase in operating speed is required without a change in the basic protocol of the system. This hybrid technique is known as isosynchronous and involves the generation of the start and stop bits associated with the asynchronous format, while still using the modem clock for bit synchronization.

The 8251 USART has been designed to meet a broad spectrum of requirements in the synchronous, asynchronous, and isosynchronous modes. In the synchronous mode the 8251 operates with 5, 6, 7, or 8-bit characters. Even or odd parity can be optionally appended and checked. Synchronization can be achieved either externally via added hardware or internally via SYN character detection. SYN detection can be based on one or two characters which may or may not be the same. The single or double SYN characters are inserted into the data stream automatically if the software fails to supply data in time. The automatic generation of SYN characters is required to prevent the loss of synchronization. In the asynchronous mode the 8251 operates with the same data and parity structures as it does in the synchronous mode. In addition to appending a START bit to this data, the

8251 appends 1, 1½, or 2 STOP bits. Proper framing is checked by the receiver and a status flag set if an error occurs. In the asynchronous mode the USART can be programmed to accept clock rates of 16 or 64 times the required baud rate. Isosynchronous operation is a special case of asynchronous with the multiplier rate programmed as one instead of 16 or 64. Note that ×1 operation is only valid if the clocks of the receiver and transmitter are synchronized.

The 8251 USART can transmit the three formats in half or full duplex mode and is double-buffered internally (i.e., the software has a complete character time to respond to a service request). Although the 8251 supports basic data set control signals (e.g., DTR and RTS), it does not fully support the signaling described in EIA-RS-232-C. Examples of unsupported signals are Carrier Detect (CF), Ring Indicator (CE), and the secondary channel signals. In some cases an additional port will be required to implement these signals. The 8251 also does not interface to the voltage levels required by EIA-RS-232-C; drivers and receivers must be added to accomplish this interface.

#### BLOCK DIAGRAM from at tampot supportionva

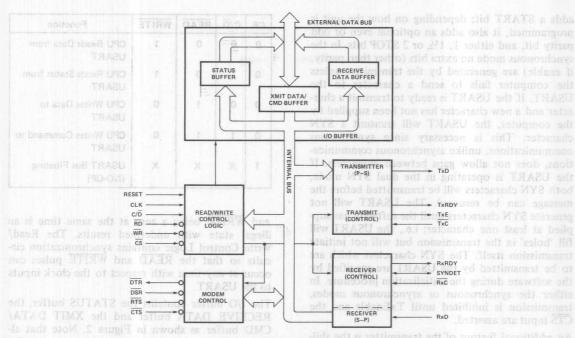

A block diagram of the 8251 is shown in Figure 2. Ås can be seen in the figure, the 8251 consists of five major sections which communicate with each other on an internal data bus. The five sections are the receiver, transmitter, modem control, read/write control, and I/O Buffer. In order to facilitate discussion, the I/O Buffer has been shown broken down into its three major subsections: the status buffer, the transmit data/command buffer, and the receive data buffer.

#### negative voltage level by RS-232-C. In our ravisos

The receiver accepts serial data on the RxD pin and converts it to parallel data according to the appropriate format. When the 8251 is in the asynchronous mode and it is ready to accept a character

AFN-00600A

2-243

TO I Stab prote Apidw englager owl one or Figure 2. 8251 Block Diagram

(i.e., it is not in the process of receiving a character), it looks for a low level on the RxD line. When it sees the low level, it assumes that it is a START bit and enables an internal counter. At a count equivalent to one-half of a bit time, the RxD line is sampled again. If the line is still low, a valid START bit has probably been received and the 8251 proceeds to assemble the character. If the RxD line is high when it is sampled, then either a noise pulse has occurred on the line or the receiver has become enabled in the middle of the transmission of a character. In either case the receiver aborts its operation and prepares itself to accept a new character. After the successful reception of a START bit the 8251 clocks in the data, parity, and STOP bits, and then transfers the data on the internal data bus to the receive data register. When operating with less than 8 bits, the characters are right-justified. The RxRDY signal is asserted to indicate that a character is available.

In the synchronous mode the receiver simply clocks in the specified number of data bits and transfers them to the receiver buffer register, setting RxRDY. Since the receiver blindly groups data bits into characters, there must be a means of synchronizing the receiver to the transmitter so that the proper character boundaries are maintained in the serial data stream. This synchronization is achieved in the HUNT mode.

In the HUNT mode the 8251 shifts in data on the

RxD line one bit at a time. After each bit is received, the receiver register is compared to a register holding the SYN character (program loaded). If the two registers are not equal, the 8251 shifts in another bit and repeats the comparison. When the registers compare as equal, the 8251 ends the HUNT mode and raises the SYNDET line to indicate that it has achieved synchronization. If the USART has been programmed to operate with two SYN characters the process is as described above. except that two contiguous characters from the line must compare to the two stored SYN characters before synchronization is declared. Parity is not checked. If the USART has been programmed to accept external synchronization, the SYNDET pin is used as an input to synchronize the receiver. The timing necessary to do this is discussed in the SIGNALS section of this note. The USART enters the HUNT mode when it is initialized into the synchronous mode or when it is commanded to do so by the command instruction. Before the receiver is operated, it must be enabled by the RxE bit (D<sub>2</sub>) of the command instructions. If this bit is not set the receiver will not assert the RxRDY bit.

#### Transmitter and off the USART's internal and also steep

The transmitter accepts parallel data from the processor, adds the appropriate framing information, serializes it, and transmits it on the TxD pin. In the asynchronous mode the transmitter always

programmed, it also adds an optional even or odd parity bit, and either 1, 1½, or 2 STOP bits. In the synchronous mode no extra bits (other than parity, if enable) are generated by the transmitter unless the computer fails to send a character to the USART. If the USART is ready to transmit a character and a new character has not been supplied by the computer, the USART will transmit a SYN character. This is necessary since synchronous communications, unlike asynchronous communications, does not allow gaps between characters. If the USART is operating in the dual SYN mode. both SYN characters will be transmitted before the message can be resumed. The USART will not generate SYN characters until the software has supplied at least one character; i.e., the USART will fill 'holes' in the transmission but will not initiate transmission itself. The SYN characters which are to be transmitted by the USART are specified by the software during the initialization procedure. In either the synchronous or asynchronous modes, transmission is inhibited until TxEnable and the CTS input are asserted.

An additional feature of the transmitter is the ability to transmit a BREAK. A BREAK is a period of continuous SPACE on the communication line and is used in full duplex communication to interrupt the transmitting terminal. The 8251 USART will transmit a BREAK condition as long as bit 3 (SBRK) of the command register is set.

# registers compare as equal, the lortnon mabom

The modem control section provides for the generation of RTS and the reception of CTS. In addition, a general purpose output and a general purpose input are provided. The output is labeled DTR and the input is labeled DSR. DTR can be asserted by setting bit 2 of the command instruction; DSR can be sensed as bit 7 of the status register. Although the USART itself attaches no special significance to these signals, DTR (Data Terminal Ready) is normally assigned to the modem, indicating that the terminal is ready to communicate and DSR (Data Set Ready) is a signal from the modem indicating that it is ready for communications.

#### of the command instructions. If this biloration O/I

The Read/Write Control Logic decodes control signals on the 8080 control bus into signals which gate data on and off the USART's internal bus and controls the external I/O bus (DB<sub>0</sub>—DB<sub>7</sub>). The truth table for these operations is as follows:

If neither READ or WRITE is a zero, then the USART will not perform an I/O function. READ

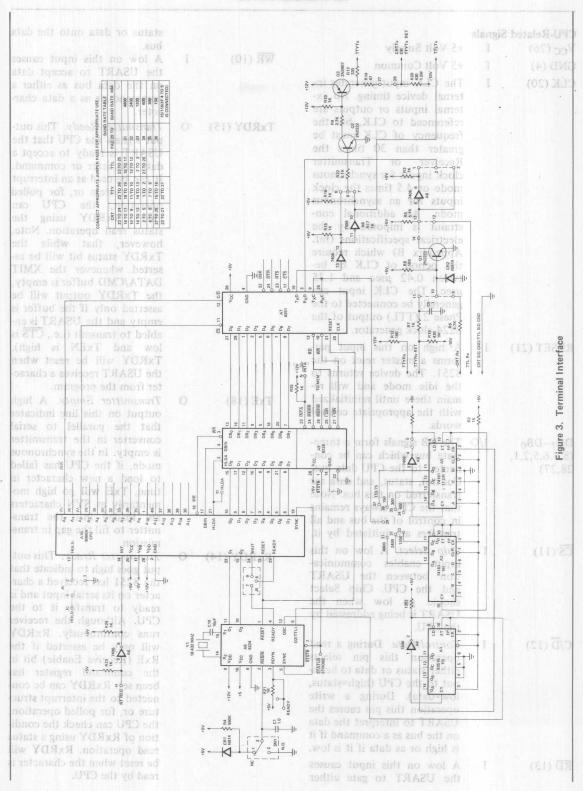

1	CE	C/D	KEAD	WRITE	Function
(	0	0	0	1	CPU Reads Data from USART
7	0	TUTA TSTR	0	1	CPU Reads Status from USART
CIRC	0	0	1	0	CPU Writes Data to USART
	0	1	1	0	CPU Writes Command to USART
	1	X	X	X	USART Bus Floating (NO-OP)

and WRITE being a zero at the same time is an illegal state with undefined results. The Read/Write Control Logic contains synchronization circuits so that the READ and WRITE pulses can occur at any time with respect to the clock inputs to the USART.

The I/O buffer contains the STATUS buffer, the RECEIVE DATA buffer and the XMIT DATA/ CMD buffer as shown in Figure 2. Note that although there are two registers which store data for transfer to the CPU (STATUS and RECEIVE DATA), there is only one register which stores data being transferred to the USART. The sharing of the input register for both transmit data and commands makes it important to ensure that the USART does not have data stored in this register before sending a command to the device. The TxRDY signal can be monitored to accomplish this. Neither data nor commands should be transferred to the USART if TxRDY is low. Failure to perform this check can result in erroneous data being transmitted.

# INTERFACE SIGNALS

The interface signals of the 8251 USART can be broken down into two groups - a CPU-related group and a device-related group. The CPU-related signals have been designed to optimize the attachment of the 8251 to a MCS-80<sup>TM</sup> system. The device-related signals are intended to interface a modem or like device. Since many peripherals (TTY, CRT, etc.) can be obtained with a modemlike interface, the USART has a broad range of applications which do not include a modem. Note that although the USART provides a logical interface to an EIA-RS-232 device, it does not provide EIA compatible drive, and this must be added via circuitry external to the 8251. As an example of a peripheral interface application and to aid in understanding the signal descriptions which follow, Figure 3 shows a system configured to interface with a TTY or CRT.

CPU-Related S					status or data onto the data

		referenced to CLK, but the frequency of CLK must be greater than 30 times the Receiver or Transmitter clock inputs for synchronous mode or 4.5 times the clock inputs for an asynchronous mode. An additional constraint is imposed by the electrical specifications (ref. Appendix B) which require the period of CLK be between 0.42 µsec and 1.35 µsec. The CLK input can generally be connected to the Phase 2 (TTL) output of the 8224 clock generator.	TxRDY (15)	0	Transmitter Ready. This output signals the CPU that the USART is ready to accept a data character or command. It can be used as an interrupt to the system or, for polled operation, the CPU can check TxRDY using the status read operation. Note, however, that while the TxRDY status bit will be asserted whenever the XMIT DATA/CMD buffer is empty, the TxRDY output will be asserted only if the buffer is empty and the USART is en-
RESET (21)	1 (26) 38 (36)	A high on this input performs a master reset on the 8251. The device returns to the idle mode and will remain there until reinitialized with the appropriate control words. During a write operation this pin causes the USART to interpret the data			runs continuously, RxRDY will only be asserted if the RxE (Receive Enable) bit in the command register has been set. RxRDY can be connected to the interrupt structure or, for polled operation,
RD (13)	I	on the bus as a command if it is high or as data if it is low.  A low on this input causes the USART to gate either			the CPU can check the condi- tion of RxRDY using a status read operation. RxRDY will be reset when the character is read by the CPU.

SYNDET (16) I/O Synch Detect. This line is used in the synchronous mode only It can be either an input or output, depending on whether the initialization program sets the USART for external or internal synchronization. SYN-DET is reset to a zero by RE-SET. When in the internal synchronization mode, the USART uses SYNDET as an output to indicate that the device has detected the required SYN character(s). A high output indicates synchronization has been achieved. If the USART is programmed to operate with double SYN characters. SYN-DET will go high in the middle of the last bit of the second SYN character. SYN-DET will be reset by a status read operation. When in the external synchronization mode a positive-going input on the SYNDET line will cause the 8251 to start assembling characters on the next falling edge of RxC. The high input should be maintained at least for one RxC cycle following (00 = od (d) about his edge. this field controls the synchronizing process. Note

Device-Related Signals DTR (24) O Data Terminal Ready. This is a notes in order value general purpose output signal of radiadw word which can be set low by pro-UTO and bloods are gramming a '1' in command instruction bit 1. This signal and notionated about allows additional device con-

appropriate SYN characte.lort, characters) must be DSR (22) I Data Set Ready. This is a genmos smas edt vd be eral purpose input signal. RTS (23) O Request to Send. This is a genanonomica et eral purpose output signal off of bourse a sequivalent to DTR. RTS is normally used to request that -small pland said mathe modem prepare itself to of Control of transmit (i.e., establish carnt myoda at noito rier). RTS can be asserted

in the command instruction CTS (17) Clear to Send. A low on this input enables the USART to transmit data. CTS is normally generated by the modem in response to a RTS.

(brought low) by setting bit 5

RxC (25) Receiver Clock. This clock controls the data rate of characters to be received by the USART. In the synchronous mode RxC is equivalent to the baud rate, and is supplied by the modem. In asynchronous mode RxC is 1, 16, or 64 times the baud rate. The clock division is preselected by the mode control instruction. Data is sampled by the USART on the rising edge of RxC.

RxD (3) Receiver Data. Characters are received serially on this pin and assembled into parallel characters. RxD is high true (i.e., High = MARK or ONE).

 $\overline{\text{TxC}}$  (9) Transmitter Clock. This clock controls the rate at which characters are transmitted by the USART. The relationship between clock rate and baud rate is the same as for RxC Data is shifted out of the USART on the falling edge of TxC

TxD (19) Transmit Data Parallel characters sent by the CPU are transmitted serially by the USART on this line. TxD is high true lorings show sall o(i.e., High = MARK or ONE).

## MODE SELECTION 2 THOU as bottsblanco ad nac

The 8251 USART is capable of operating in a number of modes (e.g., synchronous or asynchronous). In order to keep the hardware as flexible as possible (both at the chip and end product level), these operating modes are selected via a series of control outputs to the USART. These mode control outputs must occur between the time the USART is reset and the time it is utilized for data transfer. Since the USART needs this information to structure its internal logic it is essential to complete the initialization before any attempts are made at data transfer (including reading status).

A flowchart of the initialization process appears in Figure 4. The first operation which must occur following a reset is the loading of the mode control

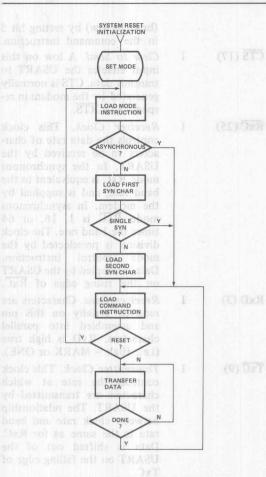

Figure 4. Initialization Flowchart

register. The mode control register is loaded by the first control output  $(C/\overline{D}=1, \overline{RD}=1, \overline{WR}=0, \overline{CS}=0)$ following a reset. The format of the mode control instruction is shown in Figure 5. The instruction can be considered as four 2-bit fields. The first 2-bit field (D<sub>1</sub> D<sub>0</sub>) determines whether the USART is to operate in the synchronous (00) or asynchronous mode. In the asynchronous mode this field also controls the clock scaling factor. As an example, if  $D_1$  and  $D_0$  are both ones, the  $\overline{RxC}$  and  $\overline{TxC}$ will be divided by 64 to establish the baud rate. The second field, D<sub>3</sub>-D<sub>2</sub>, determines the number of data bits in the character and the third, D<sub>5</sub>-D<sub>4</sub>, controls parity generation. Note that the parity bit (if enabled) is added to the data bits and is not considered as part of them when setting up the character length. As an example, standard ASCII transmission, which is seven data bits plus even parity, would be specified as:

following a resex X X 1 1 1 1 1 0 X X x see a griwoffel

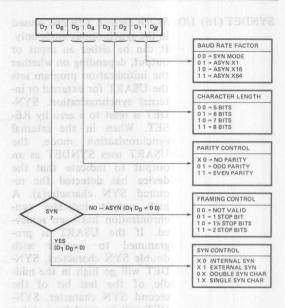

Figure 5. Mode Instruction Format

The last field, D7-D6, has two meanings, depending on whether operation is to be in the synchronous or asynchronous mode. For the asynchronous mode (i.e.,  $D_1$   $D_0 \neq 00$ ), it controls the number of STOP bits to be transmitted with the character. Since the receiver will always operate with only one STOP bit, D7 and D6 only control the transmitter. In the synchronous mode  $(D_1 D_0 = 00)$ , this field controls the synchronizing process. Note that the choice of single or double SYN characters is independent of the choice of internal or external synchronization. This is because even though the receiver may operate with external synchronization logic, the transmitter must still know whether to send one or two SYN characters should the CPU fail to supply a character in time.

Following the loading of the mode instruction the appropriate SYN character (or characters) must be loaded if synchronous mode has been specified. The SYN character(s) are loaded by the same control output instruction used to load the mode instruction. The USART determines from the mode instruction whether no, one, or two SYN characters are required and uses the control output to load SYN characters until the required number are loaded.

At completion of the load of SYN characters (or after the mode instruction in the asynchronous mode), a command character is issued to the USART. The command instruction controls the operation of the USART within the basic framework established by the mode instruction. The format of the command instruction is shown in

Figure 6. Note that if, as an example, the USART is waiting for a SYN character load and instead is issued an internal reset command, it will accept the command as a SYN character instead of resetting. This situation, which should only occur if two independent programs control the USART, can be avoided by outputting three all zero characters as commands before issuing the internal reset command. The USART indicates its state in a status register which can be read under program control. The format of the status register read is shown in Figure 7.

When operating the receiver it is important to realize that RxE (bit 2 of the command instruction) only inhibits the assertion of RxRDY; it does not inhibit the actual reception of characters. Because the receiver is constantly running, it is possible for it to contain extraneous data when it is enabled. To avoid problems this data should be read from the USART and discarded. The read should be done immediately following the setting of Receive Enable in the asynchronous mode, and following the setting of Enter Hunt in the synchronous mode. It is not necessary to wait for RxRDY before executing the dummy read.

applicance AUSUS ethicity don each and Figure 7. Status Register Format and another stable language.

#### PROCESSOR DATA LINK

The ability to change the operating mode of the USART by software makes the 8251 an ideal device to use to implement a serial communication link. A terminal initially configured with a simple asynchronous protocol can be upgraded to a synchronous protocol such as IBM Binary Synchronous Communication by a software only upgrade. In order to demonstrate the use of the 8251 USART, the remainder of this document will describe the implementation of an interrupt-driven, full duplex communication link on the Intel MDSTM system. With minor modifications, the program developed could be used on the Intel SBC-80/10<sup>TM</sup> OEM card, thus implementing a data link between the two systems. Such a facility can be used to down-load programs, run diagnostics, and maintain common data bases in multiprocessor systems.

The factors which must be considered in the design of such a link include the desired transmission rate and format, the error checking requirements, the desirability of full duplex operation, and the physical implementation of the link. The basic requirement of the system described here is that it allow an Intel SBC-80/10 OEM card to be loaded from an MDS development system, either locally or on the switched telephone network. An additional constraint is that the modem used on the switched network be readily available and inexpensive. These requirements led to the choice of a modem such as the Bell 103A to implement the link. These modems, which support full duplex communication at up to 300 baud, are readily available from a number of sources at reasonable cost. These modems are also available in acoustically coupled versions which do not require permanent installation on the telephone network. Interface to the 103A modem is accomplished with nine wires: Protective Ground, Signal Ground, Transmitted Data, Received Data, Clear to Send, Data Set Ready, Data Terminal Ready, Carrier Detector, and Ringing Indicator.

The utilization of the interface signals to the modem is as follows:

Protective	Protective Ground is used to bond
Ground	the chassis ground of the modem to
	that of the terminal.

Signal	Signal Ground provides a common
Ground	ground reference between the mo-
	dem and the terminal.

Transmitted	Transmitted Data is used to transfer
Data	serial data from the terminal to the
	modem.

Data teni bos	Received Data is used to transfer serial data from the modem to the terminal.

Data Set Ready	Data Set Ready indicates that the modem is connected to the telephone line and is in the data mode.
Data Terminal	Data Terminal Ready is a signal from the terminal which permits the modem to enter the data mode.
Carrier Y Detector Stores	Carrier Detector is identical to Clear to Send in the 103 modem and will not be used in this interface.
	from the telephone system. This signal will not be used in the interface, since it is possible for the

A block diagram showing the connections between the MDS and the SBC-80/10 through the modems is shown in Figure 8. Figure 9 shows the portion of the MDS monitor board devoted to the USARTs and Figure 10 shows the equivalent section of the SBC-80/10 board. Note that several signals on the MDS to not have the proper EIA defined voltage levels, and for this reason the adapter shown in Figure 11 was added to the MDS. The 390 pF capacitor was added to the 1488 driver to bring the rise time within EIA imposed limits of 30 volts/ usec. In Figure 7 the signal labels within the MDS and SBC-80/10 blocks correspond to the labels on the schematics, the signal labels within the modem blocks correspond to EIA conventions, and the signal labels on the wires between the blocks are abbreviations for the English language names of the signals.

As an example of how the USART clocks can be generated, circuits A27, A16, and A15 of Figure 9 form a divider of the OSC signal. The OSC signal has a frequency of 18.432 MHz and is generated by the 8224 which generates system timing for the 8080A. The 18.432 MHz signal results in a state time of 488 ns versus the normal 500 ns for the 8080A. (This does not violate 8080A specifications.) The 18.432 MHz signal can be divided by

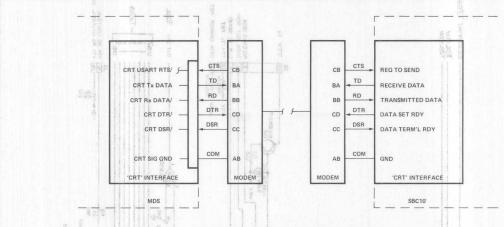

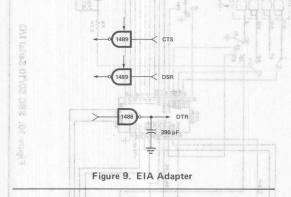

Figure 8. System Block Diagram

30 and then 64 to give a 9600 baud communication standard. The 9600 baud signal can be further divided to give 4800, 2400, 1200, 600, and 300 baud signals. The 1200 baud signal can be divided by 11 to give a 109.1 baud signal which is within 1% of the 110 baud standard signal rate. Note that because of constraints on the CLK input 9600 baud operation is not possible in the X64 mode. The divide by 64 can be accomplished by dividing by 4 with a counter and then 16 within the USART.

In order to keep the system as general purpose as possible, it was decided to transmit 8-bit data characters with an appended odd parity bit. Having a full 8-bit byte available for data enables the transmission of codes such as ASCII (which is 7-level with an additional parity bit) to be transmitted and received transparently in the system. Also, of course, it allows 8-bit bytes from the 8080A memory to be transferred in one transmission character. If error checking beyond the parity check is required, it could be added to the data record to be transmitted in the form of redundant check characters.

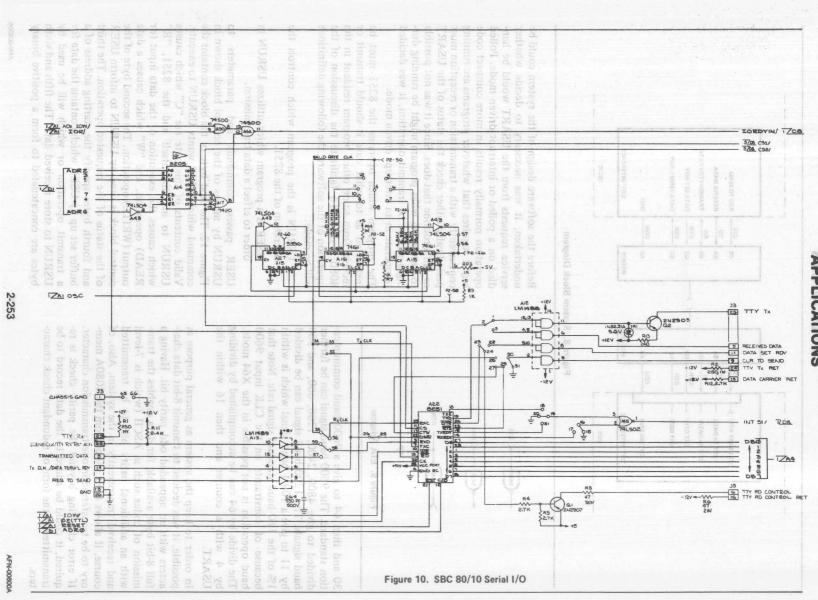

Before the software design of the system could be undertaken, it was necessary to decide whether service requests from the USART would be handled on a polled or interrupt driven mode. Polled operation normally results in more compact code but it requires that whatever programs are running concurrently with a transmission or reception must periodically either check the status of the USART or call a routine that does. Since it was not possible to determine what program might be running during a receive or transmit operation, it was decided to operate in an interrupt driven mode.

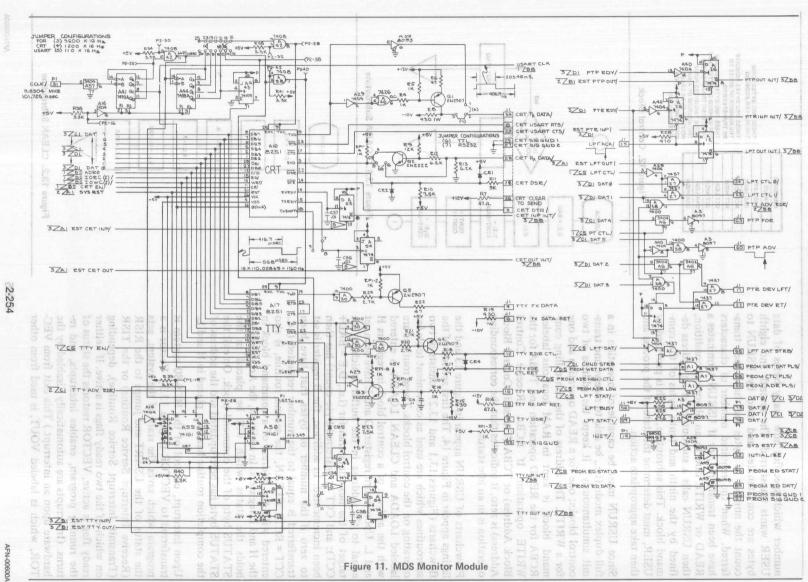

The program which operates the 8251 must be instructed as to what data it should transmit or receive from some other program resident in the 8080 system. To facilitate the discussion of the operation of the software, the following definitions will be made:

USRUN is the program which controls the operation of the 8251.

USER is a program which utilizes USRUN in order to effect a data transmission.

USER passes commands and parameters to USRUN by means of the control block shown in Figure 12. The first byte of the block contains the command which USER wants USRUN to execute. Valid contents of this byte are "C" which causes USRUN to initialize itself and the 8251, "R" which causes the execution of the data input (or READ) operation, and "W" which causes a data output (WRITE) operation. The second byte of the control block is used by USRUN to inform USER of the status of the requested operation. The third and fourth bytes specify the starting address of a buffer set up by USER which contains the data for a transmit operation or which will be used by USRUN to store received data. The fifth and sixth bytes are concatenated to form a positive binary

number which specifies how many bytes of data USER wants transferred. The seventh and eighth bytes are concatenated and used by USRUN to count the number of bytes that have been transferred. When the required number of characters have been transferred, or if USRUN terminates a READ or WRITE due to an abnormal condition, then USRUN calls a subroutine at an address defined by the ninth and tenth bytes of the command block. This subroutine, which is provided by USER, must determine the state of the process and then take appropriate action.

Since USRUN must be capable of operation in a full duplex mode (i.e., be able to receive and transmit simultaneously), it keeps the address of two control blocks; one for a READ operation and one for a WRITE. The address of the controlling command block is kept in RAM locations labeled RCBA for the READ operation and TCBA for the WRITE operation. If RCBA (Receive Control Block Address) or TCBA (Transmit Control Block Address) is zero, it indicates that the corresponding operation is in an idle status.

Flowcharts of USRUN appear in Figure 13 and the listings appear in Figure 14. The first section of the flowcharts (Figures 13.1 and 13.2) consists of two subroutines which are used as convenient tools for operating on the control blocks. These routines are labeled LOADA and CLEAN. LOADA is entered with the address of a control block in registers H and L. Upon return registers D and E have been set equal to the address in the buffer which is the target of the next data transfer (i.e., D,E = BAD+ CCT); and CCT (transferred byte count) has then been incremented. In addition, the B register is set to zero if the number of bytes that have been transferred is equal to the number requested (i.e., CCT = RCT). CLEAN, the second routine, is also entered with the address of a command block in the H and L registers. In addition, the Accumulator holds the status which will be placed in the STATUS byte of the command block. On exit the STATUS byte has been updated and the address of the completion routine has been placed in H and L.

Upon interrupt, control of the MCS-80 system is transferred to VECTOR (Figure 13.3). Vector is a program which saves the state of the system, gets the status of the USART and jumps to the RISR (Receive Interrupt Service Routine) or the TISR (Transmit Interrupt Service Routine), depending on which of the two ready flags is active. If neither ready flag is active, VECTOR restores the status of the running program, enables interrupts, and returns. (Interrupts are automatically disabled by the hardware upon an interrupt.) This exit from VEC-TOR, which is labeled VOUT, is used from other

portions of USRUN if return from the interrupt mode is required.

In addition to handling normal data transfers, TISR (Figure 13.4) checks a location in memory named TCMD in order to determine if the receive program wishes to send a command to the USART. Since the transmit data and command must share a buffer within the USART, any command output must occur when TxRDY is asserted. If TCMD is zero, TISR proceeds with the data transfer. If TCMD is non-zero, TISR calls TUTE (Transmit Utility, Figure 13.5) which, depending on the value

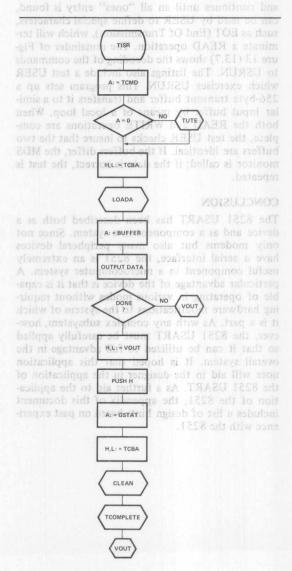

Figure 13.5. Transmit Utility Routine

The flowchart of the RISR is shown in Figure 13.6. Note that in addition to terminating whenever the required number of characters have been received, the RISR also terminates if one of the error flags becomes set or if the received character matches a character found in a table pointed to by the label ETAB. This table, which starts at ETAB and continues until an all "ones" entry is found, can be used by USER to define special characters, such as EOT (End Of Transmission), which will terminate a READ operation. The remainder of Figure 13 (13.7) shows the decoding of the commands to USRUN. The listings also include a test USER which exercises USRUN. This program sets up a 256-byte transmit buffer and transfers it to a similar input buffer by means of a local loop. When both the READ and WRITE operations are complete, the test USER checks to insure that the two buffers are identical. If the buffers differ, the MDS monitor is called; if the data is correct, the test is repeated.

#### CONCLUSION

The 8251 USART has been described both as a device and as a component in a system. Since not only modems but also many peripheral devices have a serial interface, the 8251 is an extremely useful component in a microcomputer system. A particular advantage of the device is that it is capable of operating in various modes without requiring hardware modifications to the system of which it is a part. As with any complex subsystem, however, the 8251 USART must be carefully applied so that it can be utilized to full advantage in the overall system. It is hoped that this application note will aid in the designer in the application of the 8251 USART. As a further aid to the application of the 8251, the appendix of this document includes a list of design hints based on past experience with the 8251.

ing a command it transmission is taking places.

Due to the internal structure of the USART, it is also possible to disturb the transmission if a command is sent while a SYN character is being generated by the cievice. (The USART generates a SYN if the software fails to respond to TARDY.) If this occurrence is possible in a system, commands should be transferred only when ten positive going edge is detacted on the TARDY.

 RxE only acts as a mask to RxRDY; it does not control the operation of the receiver.

When the reneiver is enabled, it is possible for it to already contain one or two characters. These characters should be read and discarded when the RxE bit is first set. Because of these extraneous characters the proper sequence for gaining extratreneixarium is as follows:

- 1. Disable inter upts
- 2. Issue a command to enter hunt mode, clear errors, and enable the receiver (EH,ER,RxE=
- 3. Read USART data (it is not necessary to check status)
  - 4. Enable interrupts

The first RARDY that occurs after the above sequence will indicate that the SYM character or

- Extraneous transitions can occur on TxEmpty while data (including USART generated SYNs) is transferred to the parallel-to-serial converter.

This situation can be avoided by ensuring that TxEmpty occurs during several consecutive status reads before assuming that the transmitter is truly in the empty state.

 A BREAK (i.e., long space) detected by the receiver results in a string of characters which have framing errors.

If reception is to be continued after a BEHAK, our must be taken to ensure that valid data is being received; special care must be taken with the last character perceived during a BREAK, since its value, including any framing error associated with it, is indeterminate.

# APPENDIX A 0000 TATE 8251 DESIGN HINTS

BUSE

1. Output of a command to the USART destroys the integrity of a transmission in progress if timed incorrectly.

Sending a command into the USART will over- #SE# 3. Loss of CTS or dropping TxEnable will immediate write any character which is stored in the buffer OAEA waiting for transfer to the parallel-to-serial converter in the device. This can be avoided by waiting for TxRDY to be asserted before sending a command if transmission is taking place. Due to the internal structure of the USART, it is also possible to disturb the transmission if a command is sent while a SYN character is being generated by the device. (The USART generates a SYN if the software fails to respond to TxRDY.) If this occurrence is possible in a system, commands should be transferred only when a positive-going edge is detected on the TxRDY line.

2. RxE only acts as a mask to RxRDY; it does not control the operation of the receiver.

When the receiver is enabled, it is possible for it to already contain one or two characters. These characters should be read and discarded when the RxE bit is first set. Because of these extraneous characters the proper sequence for gaining synchronization is as follows:

- 1. Disable interrupts
- 2. Issue a command to enter hunt mode, clear errors, and enable the receiver (EH,ER,RxE=
- 3. Read USART data (it is not necessary to check status)
- 4. Enable interrupts

The first RxRDY that occurs after the above sequence will indicate that the SYN character or characters have been detected and the next character has been assembled and is ready to be read.

ately clamp the serial output line.

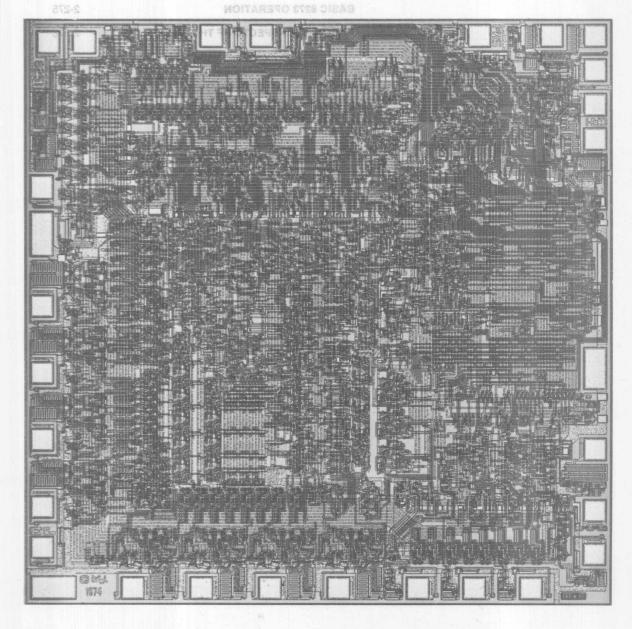

TxEnable and RTS should remain asserted until the transmission is complete. Note that this implies that not only has the USART completed the transfer of all bits of the last character, but also that they have cleared the modem. A delay of 1 msec following a proper occurrence of TxEmpty is usually sufficient (see item 4). An additional problem can occur in the synchronous mode because the loss of TxEnable clamps the data in at a SPACE instead of the normal MARK. This problem, which does not occur in the asynchronous mode, can be corrected by an external gate combining RTS and the serial output data.

- 4. Extraneous transitions can occur on TxEmpty while data (including USART generated SYNs) is transferred to the parallel-to-serial converter. This situation can be avoided by ensuring that TxEmpty occurs during several consecutive status reads before assuming that the transmitter is truly in the empty state.
- 5. A BREAK (i.e., long space) detected by the receiver results in a string of characters which have framing errors.

If reception is to be continued after a BREAK. care must be taken to ensure that valid data is being received; special care must be taken with the last character perceived during a BREAK, since its value, including any framing error associated with it, is indeterminate.

### control field, the Information field is nonocupally

The Intel 8273 is a Data Communications Protocol Controller designed for use in systems utilizing either SDLC or HDLC (Synchronous or High-Level Data Link Control) protocols. In addition to the usual features such as full duplex operation, automatic Frame Check Sequence generation and checking, automatic zero bit insertion and deletion, and TTL compatibility found on other single component SDLC controllers; the 8273 features a frame level command structure, a digital phase locked loop, SDLC loop operation, and diagnostics.

The frame level command structure is made possible by the 8273's unique internal dual processor architecture. A high-speed bit processor handles the serial data manipulations and character recognition. A byte processor implements the frame level commands. These dual processors allow the 8273 to control the necessary byte-by-byte operation of the data channel with a minimum of CPU (Central Processing Unit) intervention. For the user this means the CPU has time to take on additional tasks. The digital phase locked loop (DPLL) provides a means of clock recovery from the received data stream on-chip. This feature, along with the frame level commands, makes SDLC loop operation extremely simple and flexible. Diagnostics in the form of both data and clock loopback are available to simplify board debug and link testing. The 8273 is a dedicated function peripheral in the MCS-80/85 Microcomputer family and as such, it interfaces to the 8080/8085 system with a minimum of external hardware.

This application note explains the 8273 as a component and shows its use in a generalized loop configuration and a typical 8085 system. The 8085 system was used to verify the SDLC operation of the 8273 on an actual IBM SDLC data communications link.

The first section of this application note presents an overview of the SDLC/HDLC protocols. It is fairly tutorial in nature and may be skipped by the more knowledgeable reader. The second section describes the 8273 from a functional standpoint with explanation of the block diagram. The software aspects of the 8273, including command examples, are discussed in the third section. The fourth and fifth sections discuss a loop SDLC configuration and the 8085 system respectively.

# SDLC/HDLC OVERVIEW to sloed a bas sloed 207

SDLC is a protocol for managing the flow of information on a data communications link. In other words, SDLC can be thought of as an envelope — addressed, stamped, and containing an s.a.s.e. — in which information is transferred from location to location on a data communications link. (Please note that while SDLC is discussed specifically, all comments also apply to HDLC except where noted.) The link may be either point-to-point or multi-point, with the point-to-point configuration being either switched or nonswitched. The information flow may use either full or half duplex exchanges. With this many configurations supported, it is difficult to find a synchronous data communications application where SDLC would not be appropriate.

Aside from supporting a large number of configurations. SDLC offers the potential of a 2x increase in throughput over the presently most prevalent protocol: Bi-Sync. This performance increase is primarily due to two characteristics of SDLC: full duplex operation and the implied acknowledgement of transferred information. The performance increase due to full duplex operation is fairly obvious since, in SDLC, both stations can communicate simultaneously. Bi-Sync supports only half-duplex (twoway alternate) communication. The increase from implied acknowledgement arises from the fact that a station using SDLC may acknowledge previously received information while transmitting different information. Up to 7 messages may be outstanding before an acknowledgement is required. These messages may be acknowledged as a block rather than singly. In Bi-Sync, acknowledgements are unique messages that may not be included with messages containing information and each information message requires a separate acknowledgement. Thus the line efficiency of SDLC is superior to Bi-Sync. On a higher level, the potential of a 2x increase in performance means lower cost per unit of information transferred. Notice that the increase is not due to higher data link speeds (SDLC is actually speed independent), but simply through better line utilization.

Getting down to the more salient characteristics of SDLC; the basic unit of information on an SDLC link is that of the frame. The frame format is shown in Figure 1. Five fields comprise each frame: flag, address, control, information, and frame check sequence. The flag fields (F) form the boundary of the frame and all other fields are positionally related to one of the two flags. All frames start with an opening flag and end with a closing flag. Flags are used for frame synchronization. They also may serve as time-fill characters between frames. (There are no intraframe time-fill characters in SDLC as there are in Bi-Sync.) The opening flag serves as a reference point for the address (A) and control (C) fields. The frame check sequence (FCS) is referenced from the closing flag. All flags have the binary configuration 01111110 (7EH).

SDLC is a bit-oriented protocol, that is, the receiving station must be able to recognize a flag (or any other special character) at any time, not just on an 8-bit boundary. This, of course, implies that a frame may be N-bits in length. (The vast majority of applications tend to use frames which are multiples of 8 bits long, however.)

OPENING FLAG	ADDRESS FIELD (A)	CONTROL FIELD (C)	INFORMATION FIELD (I)	FRAME CHECK SEQUENCE (FCS)	CLOSING
01111110	8 BITS	8 BITS	ANY LENGTH 0 TO N BITS	16 BITS	0111111

Figure 1. SDLC Frame Format

received, invalidating the frame. SDLC handles this situation through a technique called zero bit insertion. This techniques specifies that within a frame a binary 0 be inserted by the transmitter after any succession of five contiguous binary 1s. Thus, no pattern of 011111110 is ever transmitted by chance. On the receiving end, after the opening flag is detected, the receiver removes any 0 following 5 consecutive 1s. The inserted and deleted 0s are not counted for error determination.

Before discussing the address field, an explanation of the roles of an SDLC station is in order. SDLC specifies two types of stations: primary and secondary. The primary is the control station for the data link and thus has responsibility of the overall network. There is only one predetermined primary station, all other stations on the link assume the secondary station role. In general, a secondary station speaks only when spoken to. In other words, the primary polls the secondaries for responses. In order to specify a specific secondary, each secondary is assigned a unique 8-bit address. It is this address that is used in the frame's address field.

When the primary transmits a frame to a specific secondary, the address field contains the secondary's address. When responding, the secondary uses its own address in the address field. The primary is never identified. This ensures that the primary knows which of many secondaries is responding since the primary may have many messages outstanding at various secondary stations. In addition to the specific secondary address, an address common to all secondaries may be used for various purposes. (An all 1s address field is usually used for this "All Parties" address.) Even though the primary may use this common address, the secondaries are expected to respond with their unique address. The address field is always the first 8 bits following the opening flag.

The 8 bits following the address field form the control field. The control field embodies the link-level control of SDLC. A detailed explanation of the commands and responses contained in this field is beyond the scope of this application note. Suffice it to say that it is in the control field that the implied acknowledgement is carried out through the use of frame sequence numbers. None of the currently available SDLC single chip controllers utilize the control field. They simply pass it to the processor for analysis. Readers wishing a more detailed explanation of the control field, or of SDLC in general, should consult the IBM documents referenced on the front page overleaf.

In some types of frames, an information field follows the control field. Frames used strictly for link management may or may not contain one. When an information field is used, it is unrestricted in both content and length. This code transparency is made possible because of the zero bit insertion mentioned earlier and the bit-oriented nature of SDLC. Even main memory core dumps may be transmitted because of this capability. This feature is unique to bit-oriented protocols. Like the

The final field is the frame check sequence (FCS). The FCS is the 16 bits immediately preceding the closing flag. This 16-bit field is used for error detection through a Cyclic Redundancy Checkword (CRC). The 16-bit transmitted CRC is the complement of the remainder obtained when the A, C, and I fields are "divided" by a generating polynomial. The receiver accumulates the A, C, and I fields and also the FCS into its internal CRC register. At the closing flag, this register contains one particular number for an error-free reception. If this number is not obtained, the frame was received in error and should be discarded. Discarding the frame causes the station to not update its frame sequence numbering. This results in a retransmission after the station sends an acknowledgement from previous frames. [Unlike all other fields, the FCS is transmitted MSB (Most Significant Bit) first. The A. C. and I fields are transmitted LSB (Least Significant Bit) first. The details of how the FCS is generated and checked is beyond the scope of this application note and since all single component SDLC controllers handle this function automatically, it is usually sufficient to know only that an error has or has not occurred. The IBM documents contain more detailed information for those readers desiring it.

The closing flag terminates the frame. When the closing flag is received, the receiver knows that the preceding 16 bits constitute the FCS and that any bits between the control field and the FCS constitute the information field.

SDLC does not support an interframe time-fill character such as the SYN character in Bi-Sync. If an unusual condition occurs while transmitting, such as data is not available in time from memory or CTS (Clear-to-Send) is lost from the modem, the transmitter aborts the frame by sending an Abort character to notify the receiver to invalidate the frame. The Abort character consists of eight contiguous 1s sent without zero bit insertion. Intraframe time-fill consists of either flags, Abort characters, or any combination of the two.

While the Abort character protects the receiver from transmitted errors, errors introduced by the transmission medium are discovered at the receiver through the FCS check and a check for invalid frames. Invalid frames are those which are not bounded by flags or are too short, that is, less than 32 bits between flags. All invalid frames are ignored by the receiver.

Although SDLC is a synchronous protocol, it provides an optional feature that allows its use on basically asynchronous data links — NRZI (Non-Return-to-Zero-Inverted) coding. NRZI coding specifies that the signal condition does not change for transmitting a binary 1, while a binary 0 causes a change of state. Figure 2 illustrates NRZI coding compared to the normal NRZ. NRZI coding guarantees that an active line will have a transition at least every 5-bit times; long strings of zeroes cause a transition every bit time, while long strings of 1s are broken up by zero bit insertion. Since asynchronous

operation requires that the receiver sampling clock be derived from the received data, NRZI encoding plus zero bit insertion make the design of clock recovery circuitry easier.

All of the previous discussion has applied to SDLC on either point-to-point or multi-point data networks, SDLC (but not HDLC) also includes specification for a loop configuration. Figure 3 compares these three configurations. IBM uses this loop configuration in its 3650 Retail Store System. It consists of a single loop controller station with one or more down-loop secondary stations. Communications on a loop rely on the secondary stations repeating a received message down loop with a delay of one bit time. The reason for the one bit delay will be evident shortly.

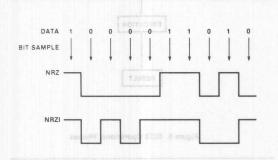

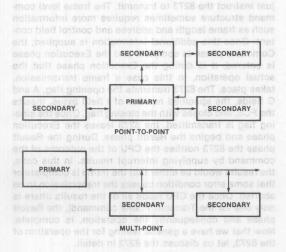

Figure 2. NRZI vs NRZ Encoding

Loop operation defines a new special character: the EOP (End-of-Poll) character which consists of a 0 followed by 7 contiguous, non-zero bit inserted, ones. After the loop controller transmits a message, it idles the line (sends all 1s). The final zero of the closing flag plus the first 7 1s of the idle form an EOP character. While repeating, the secondaries monitor their incoming line for an EOP character. When an EOP is detected, the secondary checks to see if it has a message to transmit. If it does, it changes the seventh 1 to a 0 (the one bit delay allows time for this) and repeats the modified EOP (now alias flag). After this flag is transmitted, the secondary terminates its repeater function and inserts its message (with multiple preceding flags if necessary). After the closing flag, the secondary resumes its one bit delay repeater function. Notice that the final zero of the secondary's closing flag plus the repeated 1s from the controller form an EOP for the next down-loop secondary, allowing it to insert a message if it desires.

One might wonder if the secondary missed any messages from the controller while it was inserting its own message. It does not. Loop operation is basically half-duplex. The controller waits until it receives an EOP before it transmits its next message. The controller's reception of the EOP signifies that the original message has propagated around the loop followed by any messages inserted by the secondaries. Notice that secondaries cannot communicate with one another directly, all secondary-to-secondary communication takes place by way of the controller.

SECONDARY SECONDARY LOOP

spatished dose associated a feel spatished Figure 3. Network Configurations

Loop protocol does not utilize the normal Abort character. Instead, an abort is accomplished by simply transmitting a flag character. Down loop, the receiver sees the abort as a frame which is either too short (if the abort occurred early in the frame) or one with an FCS error. Either results in a discarded frame. For more details on loop operation, please refer to the IBM documents referenced earlier.

Another protocol very similar to SDLC which the 8273 supports is HDLC (High-Level Data Link Control). There are only three basic differences between the two: HDLC offers extended address and control fields, and the HLDC Abort character is 7 contiguous 1s as opposed to SDLC's 8 contiguous 1s.

Extended addressing, beyond the 256 unique addresses possible with SDLC, is provided by using the address field's least significant bit as the extended address modifier. The receiver examines this bit to determine if the octet should be interpreted as the final address octet. As long as the bit is 0, the octet that contains it is considered an extended address. The first time the bit is a 1, the receiver interprets that octet as the final address octet. Thus the address field may be extended to any number of octets. Extended addressing is illustrated in Figure 4a.

A similar technique is used to extend the control field although the extension is limited to only one extra control octet. Figure 4b illustrates control field extension.

Those readers not yet asleep may have noticed the similarity between the SDLC loop EOP character (a 0 followed by 7 1s) and the HDLC Abort (7 1s). This possible incompatibility is neatly handled by the HDLC protocol not specifying a loop configuration.

This completes our brief discussion of the SDLC/HDLC protocols. Now let us turn to the 8273 in particular and discuss its hardware aspects through an explanation of the block diagram and generalized system schematics.

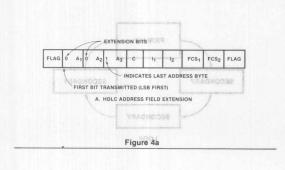

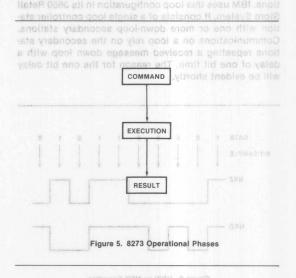

Figure 4b

### BASIC 8273 OPERATION or add tadt applicant notices

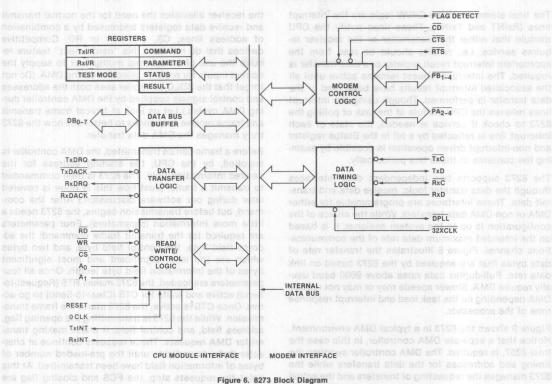

It will be helpful for the following discussions to have some idea of the basic operation of the 8273. Each operation, whether it is a frame transmission, reception or port read, etc., is comprised of three phases: the Command, Execution, and Result phases. Figure 5 shows the sequence of these phases. As an illustration of this sequence, let us look at the transmit operation.

When the CPU decides it is time to transmit a frame, the Command phase is entered by the CPU issuing a Transmit Frame command to the 8273. It is not sufficient to just instruct the 8273 to transmit. The frame level command structure sometimes requires more information such as frame length and address and control field content. Once this additional information is supplied, the Command phase is complete and the Execution phase is entered. It is during the Execution phase that the actual operation, in this case a frame transmission, takes place. The 8273 transmits the opening flag, A and C fields, the specified number of I field bytes, inserts the FCS, and closes with the closing flag. Once the closing flag is transmitted, the 8273 leaves the Execution phase and begins the Result phase. During the Result phase the 8273 notifies the CPU of the outcome of the command by supplying interrupt results. In this case, the results would be either that the frame is complete or that some error condition causes the transmission to be aborted. Once the CPU reads all of the results (there is only one for the Transmit Frame command), the Result phase and consequently the operation, is complete. Now that we have a general feeling for the operation of the 8273, let us discuss the 8273 in detail.

### HARDWARE ASPECTS OF THE 8273

The 8273 block diagram is shown in Figure 6. It consists of two major interfaces: the CPU module interface and the modem interface. Let's discuss each interface separately.

# CPU Interface bes because islant ent sette Isrii

The CPU interface consists of four major blocks: Control/Read/Write logic (C/R/W), internal registers, data transfer logic, and data bus buffers.

The CPU module utilizes the C/R/W logic to issue commands to the 8273. Once the 8273 receives a command and executes it, it returns the results (good/bad completion) of the command by way of the C/R/W logic. The C/R/W logic is supported by seven registers which are addressed via the A<sub>0</sub>, A<sub>1</sub>, RD, and WR signals, in addition to CS. The A<sub>0</sub> and A<sub>1</sub> signals are generally derived from the two low order bits of the CPU module address bus while RD and WR are the normal I/O Read and Write signals found on the system control bus. Figure 7 shows the address of each register using the C/R/W logic. The function of each register is defined as follows:

ADDRESS INPUTS		CONTROL INPUTS			
A <sub>1</sub>	A <sub>0</sub>	CS.RD	CS · WR		
0	0	STATUS	COMMAND		
0 1		RESULT	PARAMETER		
1	0	TxI/R	TEST MODE		
1	1	RxI/R	-		

Figure 7. 8273 Register Selection

Command — 8273 operations are initiated by writing the appropriate command byte into this register.

Parameter - Many commands require more information than found in the command itself. This additional information is provided by way of the parameter register. In most and teauper a fact 2728 and

Immediate Result (Result) - The completion information (results) for commands which execute immediately are provided in this register.

Transmit Interrupt Result (TxI/R) - Results of transmit operations are passed to the CPU in this register. Sylocon a lant CASS and applicant II A 258 and

Receiver Interrupt Result (RxI/R) - Receive operation results are passed to the CPU via this register.

Status — The general status of the 8273 is provided in this register. The Status register supplies the handshaking necessary during various phases of the 8273 operation. The most excellent of deline ad of

Test Mode — This register provides a software reset function for the 8273.

The commands, parameters, and bit definition of these registers are discussed in the following software section. Notice that there are not specific transmit or receive data registers. This feature is explained in the data transfer logic discussion.

The final elements of the C/R/W logic are the interrupt lines (RxINT and TxINT). These lines notify the CPU module that either the transmitter or the receiver requires service; i.e., results should be read from the appropriate interrupt result register or a data transfer is required. The interrupt request remains active until all the associated interrupt results have been read or the data transfer is performed. Though using the interrupt lines relieves the CPU module of the task of polling the 8273 to check if service is needed, the state of each interrupt line is reflected by a bit in the Status register and non-interrupt driven operation is possible by examing the contents of these bits periodically.

The 8273 supports two independent data interfaces through the data transfer logic; receive data and transmit data. These interfaces are programmable for either DMA or non-DMA data transfers. While the choice of the configuration is up to the system designer, it is based on the intended maximum data rate of the communications channel. Figure 8 illustrates the transfer rate of data bytes that are acquired by the 8273 based on link data rate. Full-duplex data rates above 9600 baud usually require DMA. Slower speeds may or may not require DMA depending on the task load and interrupt response time of the processor.

Figure 9 shows the 8273 in a typical DMA environment. Notice that a separate DMA controller, in this case the Intel 8257, is required. The DMA controller supplies the timing and addresses for the data transfers while the 8273 manages the requesting of transfers and the actual counting of the data block lengths. In this case, elements of the data transfer interface are:

TxDRQ: Transmit DMA Request — Asserted by the 8273, this line requests a DMA transfer from memory to the 8273 for transmit.

TxDACK: Transmit DMA Acknowledge — Returned by the 8257 in response to TxDRQ, this line notifies the 8273 that a request has been granted, and provides access to the transmitter data register.

RxDRQ: Receiver DMA Request — Asserted by the 8273, it requests a DMA transfer from the 8273 to memory for a receive operation.

TxDACK: Receiver DMA Acknowledge — Returned by the 8257, it notifies the 8273 that a receive DMA cycle has been granted, and provides access to the receiver data register.

RD: Read — Supplied by the 8257 to indicate data is to be read from the 8273 and placed in memory.

WR: Write — Supplied by the 8257 to indicate data is to be written to the 8273 from memory.

To request a DMA transfer the 8273 raises the appropriate DMA request line; let us assume it is a transmitter request (TxDRQ). Once the 8257 obtains control of the system bus by way of its HOLD and HLDA (hold acknowledge) lines, it notifies the 8273 that TxDRQ has been granted by returning TxDACK and WR. The TxDACK and WR signals transfer data to the 8273 for a transmit, independent of the 8273 chip select pin (CS). A similar sequence of events occurs for receiver requests. This "hard select" of data into the transmitter or out of

the receiver alleviates the need for the normal transmit and receive data registers addressed by a combination of address lines, CS, and WR or RD. Competitive devices that do not have this "hard select" feature require the use of an external multiplexer to supply the correct inputs for register selection during DMA. (Do not forget that the SDLC controller sees both the addresses and control signals supplied by the DMA controller during DMA cycles.) Let us look at typical frame transmit and frame receive sequences to better see how the 8273 truly manages the DMA data transfer.

Before a frame can be transmitted, the DMA controller is supplied, by the CPU, the starting address for the desired information field. The 8273 is then commanded to transmit a frame. (Just how this is done is covered later during our software discussion.) After the command, but before transmission begins, the 8273 needs a little more information (parameters). Four parameters are required for the transmit frame command: the address field byte, the control field byte, and two bytes which are the least significant and most significant bytes of the information field byte length. Once all four parameters are loaded, the 8273 makes RTS (Request-to-Send) active and waits for CTS (Clear-to-Send) to go active. Once CTS is active, the 8273 starts the frame transmission. While the 8273 is transmitting the opening flag, address field, and control field; it starts making transmitter DMA requests. These requests continue at character (byte) boundaries until the pre-loaded number of bytes of information field have been transmitted. At this point the requests stop, the FCS and closing flag are transmitted, and the TxINT line is raised, signaling the CPU that the frame transmission is complete. Notice that after the initial command and parameter loading. absolutely no CPU intervention was required (since DMA is used for data transfers) until the entire frame was transmitted. Now let's look at a frame reception.

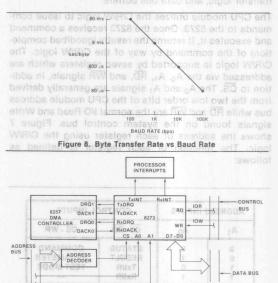

Figure 9. DMA, Interrupt-Driven System

The receiver operation is very similar. Like the initial transmit sequence, the DMA controller is loaded with a starting address for a receiver data buffer and the 8273 is commanded to receive. Unlike the transmitter, there are two different receive commands: General Receive, where all received frames are transferred to memory, and Selective Receive, where only frames having an address field matching one of two preprogrammed 8273 address fields are transferred to memory. Let's assume for now that we want to general receive. After the receive command, two parameters are required before the receiver becomes active: the least significant and most significant bytes of the receiver buffer length. Once these bytes are loaded, the receiver is active and the CPU may return to other tasks. The next frame appearing at the receiver input is transferred to memory using receiver DMA requests. When the closing flag is received, the 8273 checks the FCS and raises its RxINT line. The CPU can then read the results which indicate if the frame was error-free or not. (If the received frame had been longer than the pre-loaded buffer length, the CPU would have been notified of that occurrence earlier with a receiver error interrupt. The command description section contains a complete list of error conditions.) Like the transmit example, after the initial command, the CPU is free for other tasks until a frame is completely received. These examples have illustrated the 8273's management of both the receiver and transmitter DMA channels.

It is possible to use the DMA data transfer interface in a non-DMA interrupt-driven environment. In this case, 4 interrupt levels are used: one each for TxINT and RxINT. and one each for TxDRQ and RxDRQ. This configuration is shown in Figure 10. This configuration offers the advantages that no DMA controller is required and data requests are still separated from result (completion) reguests. The disadvantages of the configuration are that 4 interrupt levels are required and that the CPU must actually supply the data transfers. This, of course, reduces the maximum data rate compared to the configuration based strictly on DMA. This system could use an Intel 8259 8-level Priority Interrupt Controller to supply a vectored CALL (subroutine) address based on requests on its inputs. The 8273 transmitter and receiver make data requests by raising the respective DRQ line. The CPU is interrupted by the 8259 and vectored to a data transfer routine. This routine either writes (for transmit) or reads (for receive) the 8273 using the respective TxDACK or RxDACK line. As in the case above, the DACK lines serve as "hard" chip selects into and out of the 8273. (TxDACK + WR writes data into the 8273 for transmit. RxDACK + RD reads data from the 8273 for receive.) The CPU is notified of operation completion and results by way of TxINT and RxINT lines. Using the 8273, and the 8259, in this way, provides a very effective, yet simple, interrupt-driven interface.

Figure 11 illustrates a system very similar to that described above. This system utilizes the 8273 in a non-DMA data transfer mode as opposed to the two DMA approaches shown in Figures 9 and 10. In the non-DMA case, data transfer requests are made on the TxINT and RxINT lines. The DRQ lines are not used. Data transfer requests are separated from result requests by a bit in

the Status register. Thus, in response to an interrupt, the CPU reads the Status register and branches to either a result or a data transfer routine based on the status of one bit. As before, data transfers are made via using the DACK lines as chip selects to the transmitter and receiver data registers.

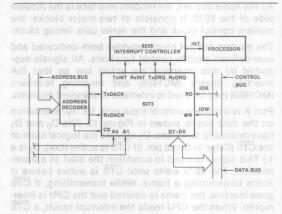

Figure 10. Interrupt-Based DMA System

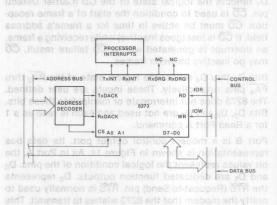

Figure 11. Non-DMA Interrupt-Driven System 10190101

Figure 12 illustrates the simplest system of all. This system utilizes polling for all data transfers and results. Since the interrupt pins are reflected in bits in the Status register, the software can read the Status register periodically looking for one of these to be set. If it finds an INT bit set, the appropriate Result Available bit is examined to determine if the "interrupt" is a data transfer or completion result. If a data transfer is called for, the DACK line is used to enter or read the data from the 8273. If the interrupt is a completion result, the appropriate result register is read to determine the good/bad completion of the operation.

The actual selection of either DMA or non-DMA modes is controlled by a command issued during initialization. This command is covered in detail during the software discussion.

The final block of the CPU module interface is the Data Bus Buffer. This block supplies the tri-state, bidirectional data bus interface to allow communication to and from the 8273.

#### Modem Interface

As the name implies, the modem interface is the modem side of the 8273. It consists of two major blocks: the modem control block and the serial data timing block.

The modem control block provides both dedicated and user-defined modem control functions. All signals supported by this interface are active low so that EIA inverting drivers (MC1488) and inverting receivers (MC1489) may be used to interface to standard modems.

Port A is a modem control input port. Its representation on the data bus is shown in Figure 13. Bits  $\mathsf{D}_0$  and  $\mathsf{D}_1$  have dedicated functions.  $\mathsf{D}_0$  reflects the logical state of the  $\overline{\text{CTS}}$  (Clear-to-Send) pin. [If  $\overline{\text{CTS}}$  is active (low),  $\mathsf{D}_0$  is a 1.] This signal is used to condition the start of a transmission. The 8273 waits until  $\overline{\text{CTS}}$  is active before it starts transmitting a frame. While transmitting, if  $\overline{\text{CTS}}$  goes inactive, the frame is aborted and the CPU is interrupted. When the CPU reads the interrupt result, a  $\overline{\text{CTS}}$  failure is indicated.

 $D_1$  reflects the logical state of the  $\overline{CD}$  (Carrier Detect) pin.  $\overline{CD}$  is used to condition the start of a frame reception.  $\overline{CD}$  must be active in time for a frame's address field. If  $\overline{CD}$  is lost (goes inactive) while receiving a frame, an interrupt is generated with a  $\overline{CD}$  failure result.  $\overline{CD}$  may go inactive between frames.

Bits  $D_2$  thru  $D_4$  reflect the logical state of the  $\overline{PA_2}$  thru  $\overline{PA_4}$  pins respectively. These inputs are user defined. The 8273 does not interrogate or manipulate these bits. Bits  $D_5$ ,  $D_6$ , and  $D_7$  are not used and each is read as a 1 for a Read Port A command.

Port B is a modern control output port. Its data bus representation is shown in Figure 14. As in Port A, the bit values represent the logical condition of the pins.  $D_0$  and  $D_5$  are dedicated function outputs.  $D_0$  represents the  $\overline{\text{RTS}}$  (Request-to-Send) pin.  $\overline{\text{RTS}}$  is normally used to notify the modern that the 8273 wishes to transmit. This function is handled automatically by the 8273. If  $\overline{\text{RTS}}$  is inactive (pin is high) when the 8273 is commanded to transmit, the 8273 makes it active and then waits for  $\overline{\text{CTS}}$  before transmitting the frame, One byte time after the end of the frame, the 8273 returns  $\overline{\text{RTS}}$  to its inactive state. However, if  $\overline{\text{RTS}}$  was active when a transmit command is issued, the 8273 leaves it active when the frame is complete.

Bit D<sub>5</sub> reflects the state of the Flag Detect pin. This pin is activated whenever an active receiver sees a flag character. This function is useful to activate a timer for line activity timeout purposes.

Bits  $D_1$  thru  $\overline{D_4}$  provide four user-defined outputs. Pins  $\overline{PB_1}$  thru  $\overline{PB_4}$  reflect the logical state of these bits. The 8273 does not interrogate or manipulate these bits.  $D_6$  and  $D_7$  are not used. In addition to being able to output to Port B, Port B may be read using a Read Port B command. All Modem control output pins are forced high on

reset. (All commands mentioned in this section are covered in detail later.).

The final block to be covered is the serial data timing block. This block contains two sections: the serial data logic and the digital phase locked loop (DPLL).

Elements of the serial data logic section are the data pins, TxD (transmit data output) and RxD (receive data input), and the respective data clocks,  $\overline{\text{TxC}}$  and  $\overline{\text{RxC}}$ . The transmit and receive data is synchronized by the  $\overline{\text{TxC}}$  and  $\overline{\text{RxC}}$  clocks. Figure 15 shows the timing for these signals. The leading edge (negative transition) of  $\overline{\text{TxC}}$  generates new transmit data and the trailing edge (positive transition) of  $\overline{\text{RxC}}$  is used to capture the receive data.

It is possible to reconfigure this section under program control to perform diagnostic functions; both data and clock loopback are available. In data loopback mode, the TxD pin is internally routed to the RxD pin. This allows simple board checkout since the CPU can send an SDLC message to itself. (Note that transmitted data will still appear on the TxD pin.)

section confeins a complete list of error condi-

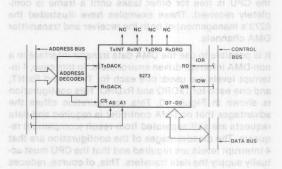

Figure 12. Polled System

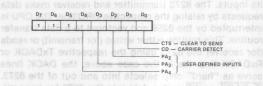

Figure 13. Port A (Input) Bit Definition

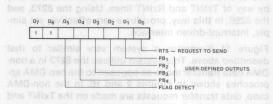

Figure 14. Port B (Output) Bit Definition

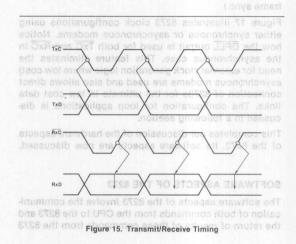

When data loopback is utilized, the receiver may be presented incorrect sample timing  $(\overline{RxC})$  by the external circuitry. Clock loopback overcomes, this problem by allowing the internal routing of  $\overline{TxC}$  and  $\overline{RxC}$ . Thus the same clock used to transmit the data is used to receive it. Examination of Figure 15 shows that this method ensures bit synchronism. The final element of the serial data logic is the Digital Phase Locked Loop.

The DPLL provides a means of clock recovery from the received data stream. This feature allows the 8273 to interface without external synchronizing logic to low cost asynchronous modems (modems which do not supply clocks). It also makes the problem of clock timing in loop configurations trivial.

To use the DPLL, a clock at 32 times the required baud rate must be supplied to the  $32 \times CLK$  pin. This clock provides the interval that the DPLL samples the received data. The DPLL uses the  $32 \times$  clock and the received data to generate a pulse at the  $\overline{DPLL}$  output pin. This  $\overline{DPLL}$  pulse is positioned at the nominal center of the received data bit cell. Thus the  $\overline{DPLL}$  output may be wired to  $\overline{RxC}$  and/or  $\overline{TxC}$  to supply the data timing. The exact position of the pulse is varied depending on the line noise and bit distortion of the received data. The adjustment of the  $\overline{DPLL}$  position is determined according to the rules outlined in Figure 16.

Adjustments to the sample phase of DPLL with respect to the received data is made in discrete increments. Referring to Figure 16, following the occurrence of DPLL pulse A, the DPLL counts 32 × CLK pulses and examines the received data for a data edge. Should no edge be detected in 32 pulses, the DPLL positions the next DPLL pulse (B) at 32 clock pulses from pulse A. Since no new phase information is contained in the data stream, the sample phase is assumed to be at nominal 1 × baud rate. Now assume a data edge occurs after

DPLL pulse B. The distance from B to the next pulse C is influenced according to which quadrant (A1, B1, B2, or A2) the data edge falls in. (Each quadrant represents 8 32 × CLK times.) For example, if the edge is detected in quadrant A<sub>1</sub>, it is apparent that pulse B was too close to the data edge and the time to the next pulse must be shortened. The adjustment for quadrant A1 is specified as -2. Thus, the next DPLL pulse, pulse C, is positioned 32-2 or 30 32 x CLK pulses following DPLL pulse B. This adjustment moves pulse C closer to the nominal bit center of the next received data cell. A data edge occurring in quadrant B2 would have caused the adjustment to be small, namely 32+1 or 33 32×CLK pulses. Using this technique, the DPLL pulse converges to the nominal bit center within 12 data transitions. worse case — 4-bit times adjusting through quadrant A<sub>1</sub> or A<sub>2</sub> and 8-bit times adjusting through B<sub>1</sub> or B<sub>2</sub>.

1 BIT TIME RyD NO TRANSITION (1 (2 2 4 6 8 10 12 14 16 18 20 22 24 26 28 30 32 2 4 6 8 10 12 14 16 18 20 22 24 26 28 30 32 DPLL 32 CLOCKS 30 CLOCKS C-2 33 CLOCKS C+1 32 CLOCKS CNOMINAL QUADRANT ADJUSTMENT A1 Figure 16. DPLL Phase Adjustments

When the receive data stream goes idle after 15 ones, DPLL pulses are generated at 32 pulse intervals of the 32x CLK. This feature allows the DPLL pulses to be used as both transmitter and receiver clocks.

In order to guarantee sufficient transitions of the received data to enable the  $\overline{DPLL}$  to lock, NRZI encoding of the data is recommended. This ensures that, within a frame, data transitions occur at least every five bit times — the longest sequence of 1s which may be transmitted with zero bit insertion. It is also recommended that frames following a line idle be transmitted with preframe sync characters which provide a minimum of 12 transitions. This ensures that the  $\overline{DPLL}$  is generating  $\overline{DPLL}$  pulses at the nominal bit centers in time for the opening flag. (Two 00H characters meet this requirement by supplying 16 transitions with NRZI encoding. The 8273 contains a mode which supplies such a preframe sync.)

Figure 17 illustrates 8273 clock configurations using either synchronous or asynchronous modems. Notice how the  $\overline{DPLL}$  output is used for both  $\overline{TxC}$  and  $\overline{RxC}$  in the asynchronous case. This feature eliminates the need for external clock generation logic where low cost) asynchronous modems are used and also allows direct connection of 8273s for the ultimate in low cost data links. The configuration for loop applications is discussed in a following section.

This completes our discussion of the hardware aspects of the 8273. Its software aspects are now discussed.

### **SOFTWARE ASPECTS OF THE 8273**

The software aspects of the 8273 involve the communication of both commands from the CPU to the 8273 and the return of results of those commands from the 8273

to the CPU. Due to the internal processor architecture of the 8273, this CPU-8273 communication is basically a form of interprocessor communication. Such communication usually requires a form of protocol of its own. This protocol is implemented through use of handshaking supplied in the 8273 Status register. The bit definition of this register is shown in Figure 18.

CBSY: Command Busy — CBSY indicates when the 8273 is in the command phase. CBSY is set when the CPU writes a command into the Command register, starting the Command phase. It is reset when the last parameter is deposited in the Parameter register and accepted by the 8273, completing the Command phase.

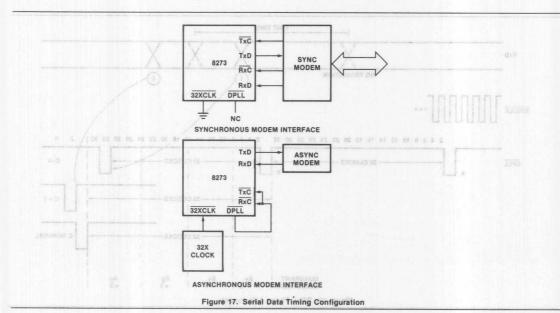

CBF: Command Buffer Full — When set, this bit indicates that a byte is present in the Command register. This bit is normally not used.

CPBF: Command Parameter Buffer Full — This bit indicates that the Parameter register contains a parameter. It is set when the CPU deposits a parameter in the Parameter register. It is reset when the 8273 accepts the parameter.

CRBF: Command Result Buffer Full — This bit is set when the 8273 places a result from an immediate type command in the Result register. It is reset when the CPU reads the result from the Result register.

RxINT: Receiver Interrupt — The state of the RxINT pin is reflected by this bit. RxINT is set by the 8273 whenever the receiver needs servicing. RxINT is reset when the CPU reads the results or performs the data transfer.

TxINT: Transmitter Interrupt — This bit is identical to RxINT except action is initiated based on transmitter interrupt sources.

2-281

RxIRA: Receiver Interrupt Result Available - RxIRA is set when the 8273 places an interrupt result byte into the RxI/R register, RxIRA is reset when the CPU reads the RxI/R register. The standard standard standard

TxIRA: Transmitter Interrupt Result Available -TxIRA is the corresponding Result Available bit for the transmitter. It is set when the 8273 places an interrupt result byte in the TxI/R register and reset when the CPU reads the register.

The significance of each of these bits will be evident shortly. Since the software requirements of each 8273 phase are essentially independent, each phase as is covered separately. The same APIXT and

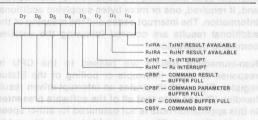

Figure 18. Status Register Format

# Command Phase Software AMD garyolome areau noit

Recalling the Command phase description in an earlier section, the CPU starts the Command phase by writing a command byte into the 8273 Command register. If further information about the command is required by the 8273, the CPU writes this information into the Parameter register. Figure 19 is a flowchart of the Command phase. Notice that the CBSY and CPBF bits of the Status register are used to handshake the command and parameter bytes. Also note that the chart shows that a command may not be issued if the Status register indicates the 8273 is busy (CBSY = 1). If a command is issued while CBSY = 1, the original command is overwritten and lost. (Remember that CBSY signifies the command phase is in progress and not the actual execution of the command.) The flowchart also includes a Parameter buffer full check. The CPU must wait until CPBF = 0 before writing a parameter to the Parameter register. If a parameter is issued while CPBF = 1, the previous parameter is overwritten and lost. An example of command output assembly language software is provided in Figure 20a. This software assumes that a command buffer exists in memory. The buffer is pointed at by the HL register. Figure 20b shows the command buffer structure.

The 8273 is a full duplex device, i.e., both the transmitter and receiver may be executing commands or passing interrupt results at any given time. (Separate Rx and Tx interrupt pins and result registers are provided for this reason.) However, there is only one Command register. Thus, the Command register must be used for only one command sequence at a time and the transmitter and receiver may never be simultaneously in a command phase. A detailed description of the commands and their parameters is presented in a following section.

Figure 20A. Command Phase Software

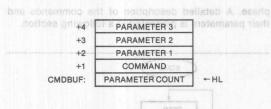

Figure 20B. Command Buffer Format

### **Execution Phase Software**

During the Execution phase, the operation specified by the Command phase is performed. If the system utilizes DMA for data transfers, there is no CPU involvement during this phase, so no software is required. If non-DMA data transfers are used, either interrupts or polling is used to signal a data transfer request.

For interrupt-driven transfers the 8273 raises the appropriate INT pin. When responding to the interrupt, the CPU must determine whether it is a data transfer request or an interrupt signaling that an operation is complete and results are available. The CPU determines the cause by reading the Status register and interrogating the associated IRA (Interrupt Result Available) bit (TX-IRA for TXINT and RXIRA for RXINT). If the IRA = 0, the interrupt is a data transfer request. If the IRA = 1, an operation is complete and the associated Interrupt Result register must be read to determine the completion status (good/bad/etc.). A software interrupt handler implementing the above sequence is presented as part of the Result phase software.

When polling is used to determine when data transfers are required, the polling routine reads the Status register looking for one of the INT bits to be set. When a set INT bit is found, the corresponding IRA bit is examined. Like in the interrupt-driven case, if the IRA = 0, a data transfer is required. If IRA = 1, an operation is complete and the Interrupt Result register needs to be read. Again, example polling software is presented in the next section.

### **Result Phase Software**

During the Result phase the 8273 notifies the CPU of the outcome of a command. The Result phase is initiated by either a successful completion of an operation or an error detected during execution. Some commands such as reading or writing the I/O ports provide immediate results, that is, there is essentially no delay from the issuing of the command and when the result is available. Other commands such as frame transmit, take time to complete so their result is not available immediately. Separate result registers are provided to distinguish these two types of commands and to avoid interrupt handling for simple results.

Immediate results are provided in the Result register. Validity of information in this register is indicated to the CPU by way of the CRBF bit in the Status register. When the CPU completes the Command phase of an immediate command, it polls the Status register waiting until CRBF = 1. When this occurs, the CPU may read the

Result register to obtain the immediate result. The Result register provides only the results from immediate commands.

Example software for handling immediate results is shown in Figure 21. The routine returns with the result in the accumulator. The CPU then uses the result as is appropriate.

All non-immediate commands deal with either the transmitter or receiver. Results from these commands are provided in the TxI/R (Transmit Interrupt Result) and RxI/R (Receive Interrupt Result) registers respectively. Results in these registers are conveyed to the CPU by the TxIRA and RxIRA bits of the Status register. Results of non-immediate commands consist of one byte result interrupt code indicating the condition for the interrupt and, if required, one or more bytes supplying additional information. The interrupt codes and the meaning of the additional results are covered following the detailed command description.

Non-immediate results are passed to the CPU in response to either interrupts or polling of the Status register. Figure 22 illustrates an interrupt-driven result handler. (Please note that all of the software presented in this application note is not optimized for either speed or code efficiency. They are provided as a guide and to illustrate concepts.) This handler provides for interruptdriven data transfers as was promised in the last section. Users employing DMA-based transfers do not need the lines where the IRA bit is tested for zero. (These lines are denoted by an asterisk in the comments column.) Note that the INT bit is used to determine when all results have been read. All results must be read. Otherwise, the INT bit (and pin) will remain high and further interrupts may be missed. These routines place the results in a result buffer pointed at by RCRBUF and

A typical result handler for systems utilizing polling is shown in Figure 23. Data transfers are also handled by this routine. This routine utilizes the routines of Figure 22 to handle the results.

At this point, the reader should have a good conceptual feel about how the 8273 operates. It is now time for the particulars of each command to be discussed.

### 8273 COMMAND DESCRIPTION

PEXIT: POP PSW

In this section, each command is discussed in detail. In order to shorten the notation, please refer to the command key in Table 1. The 8273 utilizes five different command types: Initialization/Configuration, Receive, Transmit, Reset, and Modem Control.

### Initialization/Configuration Commands

The Initialization/Configuration commands manipulate registers internal to the 8273 that define the various operating modes. These commands either set or reset specified bits in the registers depending on the type of command. One parameter is required. Set commands perform a logical OR operation of the parameter (mask) and the internal register. This mask contains 1s where register bits are to be set. A 0 in the mask causes no change in the corresponding register bit. Reset commands perform a logical AND operation of the parameter (mask) and the internal register, i.e., the mask is 0 to reset a register bit and a 1 to cause no change. Before presenting the commands, the register bit definitions are discussed.

## TABLE 1. COMMAND SUMMARY KEY

B<sub>0</sub>, B<sub>1</sub> - LSB AND MSB OF RECEIVE BUFFER LENGTH R<sub>0</sub>, R<sub>1</sub> — LSB AND MSB OF RECEIVED FRAME LENGTH Lo, L1 - LSB AND MSB OF TRANSMIT FRAME LENGTH A<sub>1</sub>, A<sub>2</sub> — MATCH ADDRESSES FOR SELECTIVE RECEIVE - RECEIVER INTERRUPT RESULT CODE - TRANSMITTER INTERRUPT RESULT CODE - ADDRESS FIELD OF RECEIVED FRAME - CONTROL FIELD OF RECEIVED FRAME

### Operating Mode Register (Figure 24) 3309 3903739439

- D<sub>7</sub>-D<sub>6</sub>: Not Used These bits must not be manipulated by any command; i.e., D<sub>7</sub>-D<sub>6</sub> must be 0 for the Set command and 1 for the Reset command.
- D<sub>5</sub>: HDLC Abort When this bit is set, the 8273 will interrupt when 7 1s (HDLC Abort) are received by an active receiver. When reset, an SDLC Abort (8 1s) will cause an interrupt.
- D<sub>4</sub>: EOP Interrupt Reception of an EOP character (0 followed by 7 1s) will cause the 8273 to interrupt the CPU when this bit is set. Loop controller stations use this mode as a signal that a polling frame has completed the loop. No EOP interrupt is generated when this bit is reset.
- D<sub>3</sub>: Early Tx Interrupt This bit specifies when the transmitter should generate an end of frame interrupt. If this bit is set, an interrupt is generated when the last data character has been passed to the 8273. If the user software issues another transmit command within two byte times, the final flag interrupt does not occur and the new frame is transmitted with only one flag of separation. If this restriction is not met, more than one flag will separate the frames and a frame complete interrupt is generated after the closing flag. If the bit is reset, only the frame complete interrupt occurs. This bit, when set, allows a single flag to separate consecutive frames.
- D<sub>2</sub>: Buffered Address and Control When set, the address and control fields of received frames are buffered in the 8273 and passed to the CPU as results after a received frame interrupt (they are not transferred to memory with the information field). On transmit, the A and C fields are passed to the 8273 as parameters. This mode simplifies buffer management. When this bit is reset, the A and C fields are passed to and from memory as the first two data transfers.
- D<sub>1</sub>: Preframe Sync When set, the 8273 prefaces each transmitted frame with two characters before the opening flag. These two characters provide 16 transitions to allow synchronization of the opposing receiver. To guarantee 16 transitions, the two characters are 55H-55H for non-NRZI mode (see Serial I/O Register description) or 00H-00H for NRZI mode. When reset, no preframe characters are transmitted.
- D<sub>0</sub>: Flag Stream When set, the transmitter will start sending flag characters as soon as it is idle; i.e., immediately if idle when the command is issued or after a transmission if the transmitter is active when this bit is set. When reset, the transmitter starts sending Idle characters on the next character boundary if idle already, or at the end of a transmission if active.

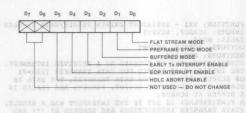

Figure 24. Operating Mode Register

### Serial I/O Mode Register (Figure 25)

- D<sub>7</sub>-D<sub>3</sub>: Not Used These bits must be 0 for the Set command and 1 for the Reset command.
- D<sub>2</sub>: Data Loopback— When set, transmitted data (TxD) is internally routed to the receive data circuitry. When reset, TxD and RxD are independent.
- D<sub>1</sub>: Clock Loopback When set, TxC is internally routed to RxC. When reset, the clocks are independent.
- D<sub>0</sub>: NRZI (Non-Return to Zero Inverted) When set, the 8273 assumes the received data is NRZI encoded, and NRZI encodes the transmitted data. When reset, the received and transmitted data are treated as a normal positive logic bit stream.

### **Data Transfer Mode Register (Figure 26)**

- D<sub>7</sub>-D<sub>1</sub>: Not Used These bits must be 0 for the Set command and 1 for the Reset command.
- D<sub>0</sub>: Interrupt Data Transfer When set, the 8273 will interrupt the CPU when data transfers are required (the corresponding IRA Status register bit will be 0 to signify a data transfer interrupt rather than a Result phase interrupt). When reset, 8273 data transfers are performed through DMA requests on the DRQ pins without interrupting the CPU.

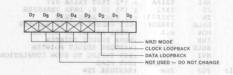

Figure 25. Serial I/O Mode Register

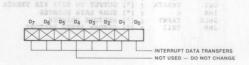

Figure 26. Data Transfer Mode Register

### One Bit Delay Register (Figure 27)

D7: One Bit Delay — When set, the 8273 retransmits the received data stream one bit delayed. This mode is entered and exited at a received character boundary. When reset, the transmitted and received data are independent. This mode is utilized for loop operation and is discussed in a later section.

D<sub>6</sub>-D<sub>0</sub>: Not Used — These bits must be 0 for the Set command and 1 for the Reset command.

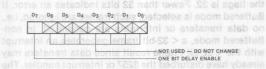

Figure 27. One Bit Delay Mode Register

Figure 28 shows the Set and Reset commands associated with the above registers. The mask which sets or resets the desired bits is treated as a single parameter. These commands do not interrupt nor provide results during the Result phase. After reset, the 8273 defaults to all of these bits reset.

REGISTER	COMMAND	HEX	PARAMETER
ONE BIT DELAY MODE	SET	A4	SET MASK
ONE BIT DELAY MODE	RESET	64	RESET MASK
DATA TRANSFER MORE	SET	97	SET MASK

Figure 28. Initialization/Configuration Command Summary

# result for this second interrupt will be a Receive Receive Command to eausal cause of the Amammon Series and the Series of the Series S

The 8273 supports three receive commands plus a receiver disable function.

### General Receive of solvies tournatri edi il igunatri

When commanded to General Receive, the 8273 passes all frames either to memory (DMA mode) or to the CPU (non-DMA mode) regardless of the contents of the frame's address field. This command is used for primary and loop controller stations. Two parameters are required: B<sub>0</sub> and B<sub>1</sub>. These parameters are the LSB and MSB of the receiver buffer size. Giving the 8273 this extra information alleviates the CPU of the burden of checking for buffer overflow. The 8273 will interrupt the CPU if the received frame attempts to overfill the allotted buffer space.

### Selective Receive

In Selective Receive, two additional parameters besides  $B_0$  and  $B_1$  are required:  $A_1$  and  $A_2$ . These parameters are two address match bytes. When commanded to Selective Receive, the 8273 passes to memory or the CPU only those frames having an address field matching either  $A_1$  or  $A_2$ . This command is usually used for secondary stations with  $A_1$  being the secondary address and  $A_2$  is the "All Parties" address. If only one match byte is needed,  $A_1$  and  $A_2$  should be equal. As in General Receive, the 8273 counts the incoming data bytes and interrupts the CPU if  $B_0$ ,  $B_1$  is exceeded.

### Selective Loop Receive

This command is very similar in operation to Selective Receive except that One Bit Delay mode must be set and that the loop is captured by placing transmitter in Flag Stream mode automatically after an EOP character is detected following a selectively received frame. The details of using the 8273 in loop configurations is discussed in a later section so please hold questions until then

The handling of interrupt results is common among the three commands. When a frame is received without error, i.e., the FCS is correct and  $\overline{\text{CD}}$  (Carrier Detect) was active throughout the frame or no attempt was made to overfill the buffer; the 8273 interrupts the CPU following the closing flag to pass the completion results. These results, in order, are the receiver interrupt result code (RIC), and the byte length of the information field of the received frame (R<sub>0</sub>, R<sub>1</sub>). If Buffered mode is selected, the address and control fields are passed as two additional results. If Buffered mode is not selected, the address and control fields are passed as the first two data transfers and R<sub>0</sub>, R<sub>1</sub> reflect the information field length plus two.

# Receive Disable tem tolbus AMQ nolingeder email dose

The receiver may also be disabled using the Receive Disable command. This command terminates any receive operation immediately. No parameters are required and no results are returned.

The details for the Receive command are shown in Figure 29. The interrupt result code key is shown in Figure 30. Some explanation of these result codes is appropriate.

The interrupt result code is the first byte passed to the CPU in the RxI/R register during the Result phase. Bits  $D_4$ – $D_0$  define the cause of the receiver interrupt. Since each result code has specific implications, they are discussed separately below.

error conditions.) Note that the FCS, either transmitted or

Figure 30. Receiver Interrupt Result Codes (RIC)

The first two result codes result from the error-free reception of a frame. If the frame is received correctly after a General Receive command, the first result is returned. If either Selective Receive command was used (normal or loop), a match with A1 generates the first result code and a match with A2 generates the second. In either case, the receiver remains active after the interrupt; however, the internal buffer size counters are not reset. That is, if the receive command indicated 100 bytes were allocated to the receive buffer (B0, B1) and an 80-byte frame was received correctly, the maximum next frame size that could be received without recommanding the receiver (resetting Bo and B1) is 20 bytes. Thus, it is common practice to recommand the receiver after each frame reception. DMA and/or memory pointers are usually updated at this time. (Note that users who do not wish to take advantage of the 8273's buffer management features may simply use B<sub>0</sub>, B<sub>1</sub> = 0FFH for each receive command. Then frames of 65K bytes may be received without buffer overflow errors.)

The third result code is a CRC error. This indicates that a frame was received in the correct format (flags, etc.); however, the received FCS did not check with the internally generated FCS. The frame should be discarded. The receiver remains active. (Do not forget that even though an error condition has been detected, all frame information up until that error has either been transferred to memory or passed to the CPU. This information should be invalidated. This applies to all receiver error conditions.) Note that the FCS, either transmitted or received, is never available to the CPU.

The Abort Detect result occurs whenever the receiver sees either an SDLC (8 1s) or an HDLC (7 1s), depending on the Operating Mode register. However, the intervening Abort character between a closing flag and an Idle does not generate an interrupt. If an Abort character (seen by an active receiver within a frame) is not preceded by a flag and is followed by an Idle, an interrupt will be generated for the Abort, followed by an Idle inter-

rupt one character time later. The Idle Detect result occurs whenever 15 consecutive 1s are received. After the Abort Detect interrupt, the receiver remains active. After the Idle Detect interrupt, the receiver is disabled and must be recommanded before further frames may be received.

If the EOP Interrupt bit is set in the Operating Mode register, the EOP Detect result is returned whenever an EOP character is received. The receiver is disabled, so the Idle following the EOP does not generate an Idle Detect interrupt.

The minimum number of bits in a valid frame between the flags is 32. Fewer than 32 bits indicates an error. If Buffered mode is selected, such frames are ignored, i.e., no data transfers or interrupts are generated. In non-Buffered mode, a < 32-bit frame generates an interrupt with the < 32-bit Frame result since data transfers may already have disturbed the 8257 or interrupt handler. The receiver remains active.

The DMA Overrun result results from the  $\overline{DMA}$  controller being too slow in extracting data from the 8273, i.e., the  $\overline{RxDACK}$  signal is not returned before the next received byte is ready for transfer. The receiver is disabled if this error condition occurs.

The Memory Buffer Overflow result occurs when the number of received bytes exceeds the receiver buffer length supplied by the  $B_0$  and  $B_1$  parameters in the receive command. The receiver is disabled.

The Carrier Detect Failure result occurs when the  $\overline{CD}$  pin goes high (inactive) during reception of a frame. The  $\overline{CD}$  pin is used to qualify reception and must be active by the time the address field starts to be received. If  $\overline{CD}$  is lost during the frame, a  $\overline{CD}$  Failure interrupt is generated and the receiver is disabled. No interrupt is generated if  $\overline{CD}$  goes inactive between frames.

If a condition occurs requiring an interrupt be generated before the CPU has finished reading the previous interrupt results, the second interrupt is generated after the current Result phase is complete (the RxINT pin and status bit go low then high). However, the interrupt result for this second interrupt will be a Receive Interrupt Overrun. The actual cause of the second interrupt is lost. One case where this may occur is at the end of a received frame where the line goes idle. The 8273 generates a received frame interrupt after the closing flag and then 15-bit times later, generates an Idle Detect interrupt. If the interrupt service routine is slow in reading the first interrupt's results, the internal RxI/R register still contains result information when the Idle Detect interrupt occurs. Rather than wiping out the previous results, the 8273 adds a Receive Interrupt Overrun result as an extra result. If the system's interrupt structure is such that the second interrupt is not acknowledged (interrupts are still disabled from the first interrupt), the Receive Interrupt Overrun result is read as an extra result, after those from the first interrupt. If the second interrupt is serviced, the Receive Interrupt Overrun is returned as a single result. (Note that the INT pins supply the necessary transitions to support a Program-

2-287

mable Interrupt Controller such as the Intel 8259. Each interrupt generates a positive-going edge on the appropriate INT pin and the high level is held until the interrupt is completely serviced.) In general, it is possible to have interrupts occurring at one character time intervals. Thus the interrupt handling software must have at least that much response and service time.

The occurrence of Receive Interrupt Overruns is an indication of marginal software design; the system's interrupt response and servicing time is not sufficient for the data rates being attempted. It is advisable to configure the interrupt handling software to simply read the interrupt results, place them into a buffer, and clear the interrupt as quickly as possible. The software can then examine the buffer for new results at its leisure, and take appropriate action. This can easily be accomplished by using a result buffer flag that indicates when new results are available. The interrupt handler sets the flag and the main program resets it once the results are retrieved.

Both SDLC and HDLC allow frames which are of arbitrary length (>32 bits). The 8273 handles this N-bit reception through the high order bits ( $D_7$ – $D_5$ ) of the result code. These bits code the number of valid received bits in the last received information field byte. This coding is shown in Figure 30. The high order bits of the received partial btye are indeterminate. [The address, control, and information fields are transmitted least significant bit ( $A_0$ ) first. The FCS is complemented and transmitted most significant bit first.]

## Transmit Commands bus session AO labigo a session

The 8273 transmitter is supported by three Transmit commands and three corresponding Abort commands.

# Transmit Frame of large to not safeulli dis as babiyong

The Transmit Frame command simply transmits a frame. Four parameters are required when Buffered mode is selected and two when it is not. In either case, the first two parameters are the least and the most significant bytes of the desired frame length ( $L_0$ ,  $L_1$ ). In Buffered mode,  $L_0$  and  $L_1$  equal the length in bytes of the desired information field, while in the non-Buffered mode,  $L_0$  and  $L_1$  must be specified as the information field length plus two. ( $L_0$  and  $L_1$  specify the number of data transfers to be performed.) In Buffered mode, the address and control fields are presented to the transmitter as the third and fourth parameters respectively. In non-Buffered mode, the A and C fields must be passed as the first two data transfers.

When the Transmit Frame command is issued, the 8273 makes RTS (Request-to-Send) active (pin low) if it was not already. It then waits until CTS (Clear-to-Send) goes active (pin low) before starting the frame. If the Preframe Sync bit in the Operting Mode register is set, the transmitter prefaces two characters (16 transitions) before the opening flag. If the Flag Stream bit is set in the Operating Mode register, the frame (including Preframe Sync if selected) is started on a flag boundary. Otherwise the frame starts on a character boundary.

At the end of the frame, the transmitter interrupts the CPU (the interrupt results are discussed shortly) and returns to either Idle or Flag Stream, depending on the Flag Stream bit of the Operating Mode register. If RTS was active before the transmit command, the 8273 does not change it. If it was inactive, the 8273 will deactivate it within one character time.

# Loop Transmit peles at about bereftuß-non it sernant

Loop Transmit is similar to Frame Transmit (the parameter definition is the same). But since it deals with loop configurations, One Bit Delay mode must be selected.

If the transmitter is not in Flag Stream mode when this command is issued, the transmitter waits until after a received EOP character has been converted to a flag (this is done automatically) before transmitting. (The one bit delay is, of course, suspended during transmit.) If the transmitter is already in Flag Stream mode as a result of a selectively received frame during a Selective Loop Receive command, transmission will begin at the next flag boundary for Buffered mode or at the third flag boundary for non-Buffered mode. This discrepancy is to allow time for enough data transfers to occur to fill up the internal transmit buffer. At the end of a Loop Transmit, the One Bit Delay mode is re-entered and the flag stream mode is reset. More detailed loop operation is covered later. note however that no Abort Complete

# Transmit Transparent Stransparent Stranspare

The Transmit Transparent command enables the 8273 to transmit a block of raw data. This data is without SDLC protocol, i.e., no zero bit insertion, flags, or FCS. Thus it is possible to construct and transmit a Bi-Sync message for front-end processor switching or to construct and transmit an SDLC message with incorrect FCS for diagnostic purposes. Only the  $L_0$  and  $L_1$  parameters are used since there are not fields in this mode. (the 8273 does not support a Receive Transparent command.)

# Abort Commands us ин вязтамавая за отвежая заа о ома а-

Each of the above transmit commands has an associated Abort command. The Abort Frame Transmit command causes the transmitter to send eight contiguous ones (no zero bit insertion) immediately and then revert to either idle or flag streaming based on the Flag Stream bit. (The 8 1s as an Abort character is compatible with both SDLC and HDLC.)

For Loop Transmit, the Abort Loop Transmit command causes the transmitter to send one flag and then revert to one bit delay. Loop protocol depends upon FCS errors to detect aborted frames.

The Abort Transmit Transparent simply causes the transmitter to revert to either idles or flags as a function of the Flag Stream mode specified.

The Abort commands require no parameters, however, they do generate an interrupt and return a result when complete.

A summary of the Transmit commands is shown in Figure 31. Figure 32 shows the various transmit interrupt result codes. As in the receiver operation, the transmitter generates interrupts based on either good

completion of an operation or an error condition to start the Result phase.

The Early Transmit Interrupt result occurs after the last data transfer to the 8273 if the Early Transmit Interrupt bit is set in the Operating Mode register. If the 8273 is commanded to transmit again within two character times, a single flag will separate the frames. (Buffered mode must be used for a single flag to separate the frames. If non-Buffered mode is selected, three flags will separate the frames.) If this time constraint is not met, another interrupt is generated and multiple flags or idles will separate the frames. The second interrupt is the normal Frame Transmit Complete interrupt. The Frame Transmit Complete result occurs at the closing flag to signify a good completion.

The DMA Underrun result is analogous to the DMA Overrun result in the receiver. Since SDLC does not support intraframe time fill, if the DMA controller or CPU does not supply the data in time, the frame must be aborted. The action taken by the transmitter on this error is automatic. It aborts the frame just as if an Abort command had been issued.

Clear-to-Send Error result is generated if  $\overline{\text{CTS}}$  goes inactive during a frame transmission. The frame is aborted as above.

The Abort Complete result is self-explanatory. Please note however that no Abort Complete interrupt is generated when an automatic abort occurs. The next command type consists of only one command.

### Reset Command In Indianate Hannat Hoda and

The Reset command provides a software reset function for the 8273. It is a special case and does not utilize the normal command interface. The reset facility is provided in the Test Mode register. The 8273 is reset by simply outputting a 01H followed by a 00H to the Test Mode register. Writing the 01 followed by the 00 mimicks the action required by the hardware reset. Since the 8273 requires time to process the reset internally, at least 10 cycles of the ØCLK clock must occur between the

writing of the 01 and the 00. The action taken is the same as if a hardware reset is performed, namely:

- 1. The modem control outputs are forced high inactive).
  - 2. The 8273 Status register is cleared.
  - 3. Any commands in progress cease.
  - The 8273 enters an idle state until the next command is issued.

#### Modem Control Commands

The modem control ports were discussed earlier in the Hardware section. The commands used to manipulate these ports are shown in Figure 33. The Read Port A and Read Port B commands are immediate. The bit definition for the returned byte is shown in Figures 13 and 14. Do not forget that the returned value represents the logical condition of the pin, i.e., pin active (low) = bit set.

PORT	COMMAND	HEX	PARAMETER	REG RESULT
A INPUT	READ	22	NONE	PORT VALUE
100-10	READ	23	NONE	PORT VALUE
B OUTPUT	SET 9	A3	SET MASK	NONE
blail no	RESET	63	RESET MASK	NONE

Figure 33. Modem Control Command Summary

The Set and Reset Port B commands are similar to the Initialization commands in that they use a mask parameter which defines the bits to be changed. Set Port B utilizes a logical OR mask and Reset Port B uses a logical AND mask. Setting a bit makes the pin active (low), Resetting the bit deactivates the pin (high).

To help clarify the numerous timing relationships that occur and their consequences, Figures 34 and 35 are provided as an illustration of several typical sequences. It is suggested that the reader go over these diagrams and re-read the appropriate part of the previous sections if necessary.

### HLDC CONSIDERATIONS lead only to selved insollingle

The 8273 supports HDLC as well as SDLC. Let's discuss how the 8273 handles the three basic HDLC/SDLC differences: extended addressing, extended control, and the 7 1s Abort character.

Recalling Figure 4A, HDLC supports an address field of indefinite length. The actual amount of extension used is determined by the least significant bit of the characters immediately following the opening flag. If the LSB is 0, more address field bytes follow. If the LSB is 1, this byte is the final address field byte. Software must be used to determine this extension.

If non-Buffered mode is used, the A, C, and I fields are in memory. The software must examine the initial characters to find the extent of the address field. If Buffered mode is used, the characters corresponding to the SDLC A and C fields are transferred to the CPU as interrupt results. Buffered mode assumes the two characters following the opening flag are to be transferred as interrupt results regardless of content or meaning. (The 8273

does not know whether it is being used in an SDLC or an HDLC environment.) In SDLC, these characters are necessarily the A and C field bytes, however in HDLC, their meaning may change depending on the amount of extension used. The software must recognize this and examine the transferred results as possible address field extensions.

Frames may still be selectively received as is needed for secondary stations. The Selective Receive command is still used. This command qualifies a frame reception on the first byte following the opening flag matching either of the  $A_1$  or  $A_2$  match byte parameters. While this does not allow qualification over the complete range of HDLC addresses, it does perform a qualification on the first address byte. The remaining address field bytes, if any, are then examined via software to completely qualify the frame.

Once the extent of the address field is found, the following bytes form the control field. The same LSB test used for the address field is applied to these bytes to determine the control field extension, up to two bytes maximum. The remaining frame bytes in memory represent the information field.

The Abort character difference is handled in the Operating Mode register. If the HDLC Abort Enable bit is set, the reception of seven contiguous ones by an active receiver will generate an Abort Detect interrupt rather than eight ones. (Note that both the HDLC Abort Enable bit and the EOP Interrupt bit must not be set simultaneously.)

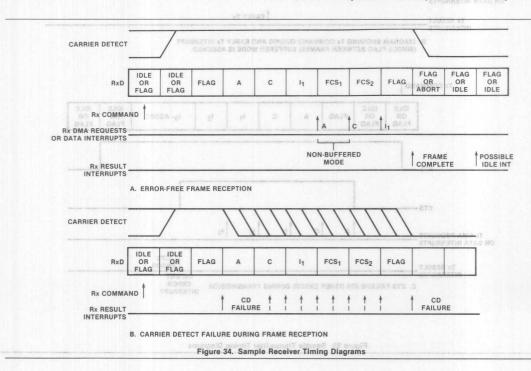

Now let's move on to the SDLC loop configuration discussion.

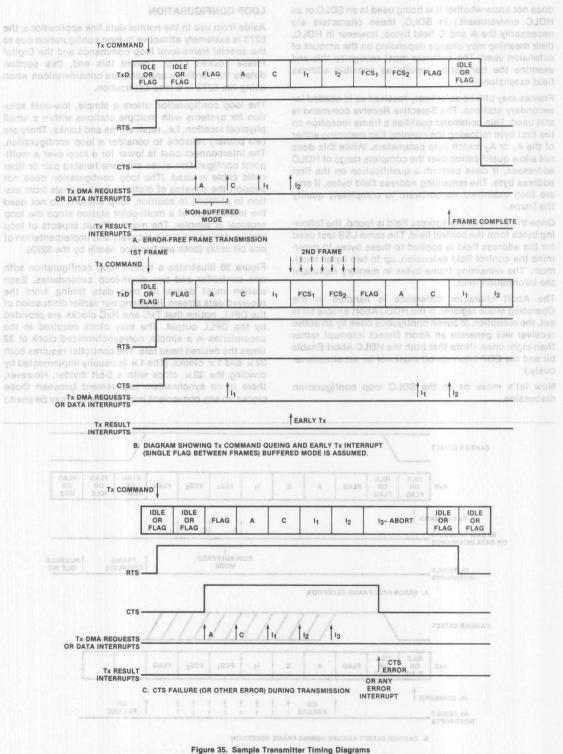

#### LOOP CONFIGURATION

Aside from use in the normal data link applications, the 8273 is extremely attractive in loop configuration due to the special frame-level loop commands and the Digital Phase Locked Loop. Toward this end, this section details the hardware and software considerations when using the 8273 in a loop application.

The loop configuration offers a simple, low-cost solution for systems with multiple stations within a small physical location, i.e., retail stores and banks. There are two primary reasons to consider a loop configuration. The interconnect cost is lower for a loop over a multipoint configuration since only one twisted pair or fiber optic cable is used. (The loop configuration does not support the passing of distinct clock signals from station to station.) In addition, loop stations do not need the intelligence of a multi-point station since the loop protocal is simpler. The most difficult aspects of loop station design are clock recovery and implementation of one bit delay (both are handled neatly by the 8273).

Figure 36 illustrates a typical loop configuration with one controller and two down-loop secondaries. Each station must derive its own data timing from the received data stream. Recalling our earlier discussion of the DPLL, notice that TxC and RxC clocks are provided by the DPLL output. The only clock required in the secondaries is a simple, non-synchronized clock at 32 times the desired baud rate. The controller requires both 32 x and 1 x clocks. (The 1 x is usually implemented by dividing the 32 x clock with a 5-bit divider. However, there is no synchronism requirement between these clocks so any convenient implementation may be used.)

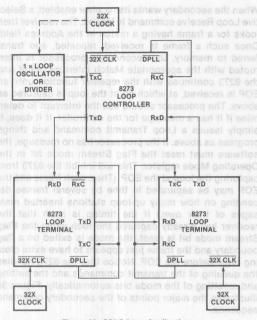

Figure 36. SDLC Loop Application

A quick review of loop protocol is appropriate. All communication on the loop is controlled by the loop controller. When the controller wishes to allow the secondaries to transmit, it sends a polling frame (the control field contains a poll code) followed by an EOP (End-Foll) character. The secondaries use the EOP character to capture the loop and insert a response frame as will be discussed shortly.

The secondaries normally operate in the repeater mode, retransmitting received data with one bit time of delay. All received frames are repeated. The secondary uses the one bit time of delay to capture the loop.

When the loop is idle (no frames), the controller transmits continuous flag characters. This keeps transitions on the loop for the sake of down-loop phase locked loops. When the controller has a non-polling frame to transmit, it simply transmits the frame and continues to send flags. The non-polling frame is then repeated around the loop and the controller receives it to signify a complete traversal of the loop. At the particular secondary addressed by the frame, the data is transferred to memory while being repeated. Other secondaries simply repeat it.

If the controller wants to poll the secondaries, it transmits a polling frame followed by all 1s (no zero bit insertion). The final zero of the closing frame plus the first seven 1s form an EOP. While repeating, the secondaries monitor their incoming line for an EOP. When an EOP is received, the secondary checks if it has any response for the controller. If not, it simply continues repeating. If the secondary has a response, it changes the seventh EOP one into a zero (the one bit time of delay allows time for this) and repeats it, forming a flag for the down-loop stations. After this flag is transmitted,

the secondary terminates its repeater function and inserts its response frame (with multiple preceding flags if necessary). After the closing flag of the response, the secondary re-enters its repeater function, repeating the up-loop controller 1s. Notice that the final zero of the response's closing flag plus the repeated 1s from the controller form a new EOP for the next down-loop secondary. This new EOP allows the next secondary to insert a response if it desires. This gives each secondary a chance to respond.

Back at the controller, after the polling frame has been transmitted and the continuous 1s started, the controller waits until it receives an EOP. Receiving an EOP signifies to the controller that the original frame has propagated around the loop followed by any responses inserted by the secondaries. At this point, the controller may either send flags to idle the loop or transmit the next frame. Let's assume that the loop is implemented completely with the 8273s and describe the command flows for a typical controller and secondary.

The loop controller is initialized with commands which specify that the NRZI, Preframe Sync, Flag Stream, and EOP Interrupt modes are set. Thus, the controller encodes and decodes all data using NRZI format. Preframe Sync mode specifies that all transmitted frames be prefaced with 16 line transitions. This ensures that the minimum of 12 transitions needed by the DPLLs to lock after an all 1s line have occurred by the time the secondary sees a frame's opening flag. Setting the Flag Stream mode starts the transmitter sending flags which idles the loop. And the EOP Interrupt mode specifies that the controller processor will be interrupted whenever the active receiver sees an EOP, indicating the completion of a poll cycle.

When the controller wishes to transmit a non-polling frame, it simply executes a Frame Transmit command. Since the Flag Stream mode is set, no EOP is formed after the closing flag. When a polling frame is to be transmitted, a General Receive command is executed first. This enables the receiver and allows reception of all incoming frames; namely, the original polling frame plus any response frames inserted by the secondaries. After the General Receive command, the frame is transmitted with a Frame Transmit command. When the frame is complete, a transmitter interrupt is generated. The loop controller processor uses this interrupt to reset Flag Stream mode. This causes the transmitter to start sending all 1s. An EOP is formed by the last flag and the first 7 1s. This completes the loop controller transmit sequence.

At any time following the start of the polling frame transmission the loop controller receiver will start receiving frames. (The exact time difference depends, of course, on the number of down-loop secondaries due to each inserting one bit time of delay.) The first received frame is simply the original polling frame. However, any additional frames are those inserted by the secondaries. The loop controller processor knows all frames have been received when it sees an EOP Interrupt. This interrupt is generated by the 8273 since the EOP Interrupt mode was set during initialization. At this point, the transmitter may be commanded either to enter Flag

Stream mode, idling the loop, or to transmit the next frame. A flowchart of the above sequence is shown in Figure 37.

The secondaries are initialized with the NRZI and One Bit Delay modes set. This puts the 8273 into the repeater mode with the transmitter repeating the received data with one bit time of delay. Since a loop station cannot transmit until it sees and EOP character, any transmit command is gueued until an EOP is received. Thus whenever the secondary wishes to transmit a response, a Loop Transmit command is issued. The 8273 then waits until it receives an EOP. At this point, the receiver changes the EOP into a flag, repeats it, resets One Bit Delay mode stopping the repeater function, and sets the transmitter into Flag Stream mode. This captures the loop. The transmitter now inserts its message. At the closing flag, Flag Stream mode is reset, and One Bit Delay mode is set, returning the 8273 to repeater function and forming an EOP for the next down-loop station. These actions happen automatically after a Loop Transmit command is issued, lini ai reflorance gool enT

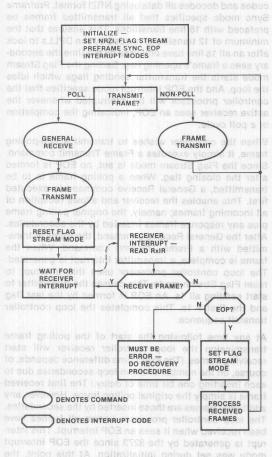

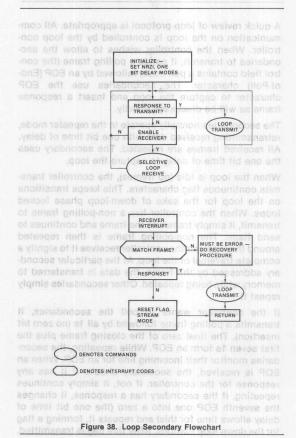

Figure 37. Loop Controller Flowchart

When the secondary wants its receiver enabled, a Selective Loop Receive command is issued. The receiver then looks for a frame having a match in the Address field. Once such a frame is received, repeated, and transferred to memory, the secondary's processor is interrupted with the appropriate Match interrupt result and the 8273 continues with the repeater function until an EOP is received, at which point the loop is captured as above. The processor should use the interrupt to determine if it has a message for the controller. If it does, it simply issues a Loop Transmit command and things progress as above. If the processor has no message, the software must reset the Flag Stream mode bit in the Operating Mode register. This will inhibit the 8273 from capturing the loop at the EOP. (The match frame and the EOP may be separated in time by several frames depending on how many up-loop stations inserted messages of their own.) If the timing is such that the receiver has already captured the loop when the Flag Stream mode bit is reset, the mode is exited on a flag boundary and the frame just appears to have extra closing flags before the EOP. Notice that the 8273 handles the queuing of the transmit commands and the setting and resetting of the mode bits automatically. Figure 38 illustrates the major points of the secondary command sequence.

2-293

When an off-line secondary wishes to come on-line, it must do so in a manner which does not disturb data on the loop. Figure 39 shows a typical hardware interface. The line labeled Port could be one of the 8273 Port B outputs and is assumed to be high (1) initially. Thus up-loop data is simply passed down-loop with no delay; however, the receiver may still monitor data on the loop. To come on-line, the secondary is initialized with only the EOP Interrupt mode set. The up-loop data is then monitored until an EOP occurs. At this point, the secondary's CPU is interrupted with an EOP interrupt. This signals the CPU to set One Bit Delay mode in the 8273 and then to set Port low (active). These actions switch the secondary's one bit delay into the loop. Since after the EOP only 1s are traversing the loop, no loop disturbance occurs. The secondary now waits for the next EOP, captures the loop, and inserts a "new on-line" message. This signals the controller that a new secondary exists and must be acknowledged. After the secondary receives its acknowledgement, the normal command flow is used.

It is hopefully evident from the above discussion that the 8273 offers a very simple and easy to implement solution for designing loop stations whether they are controllers or down-loop secondaries.

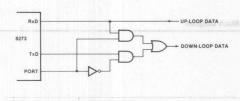

Figure 39. Loop Interface

### APPLICATION EXAMPLE

This section describes the hardware and software of the 8273/8085 system used to verify the 8273 implementation of SDLC on an actual IBM SDLC Link. This IBM link was gratefully volunteered by Raytheon Data Systems in Norwood, Mass. and I wish to thank them for their generous cooperation. The IBM system consisted of a 370 Mainframe, a 3705 Communications Processor, and a 3271 Terminal Controller. A Comlink II Modem supplied the modem interface and all communications took place at 4800 baud. In addition to observing correct responses, a Spectron D601B Datascope was used to verify the data exchanges. A block diagram of the system is shown in Figure 40. The actual verification was accomplished by the 8273 system receiving and responding to polls from the 3705. This method was ed on both point-to-point and multi-point configuras. No attempt was made to implement any higher ol software over that of the poll and poll resince such software would not affect the verithe 8273 implementation. As testimony to the

of the 8273, the system worked on the first

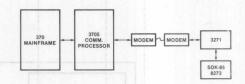

Figure 40. Raytheon Block Diagram

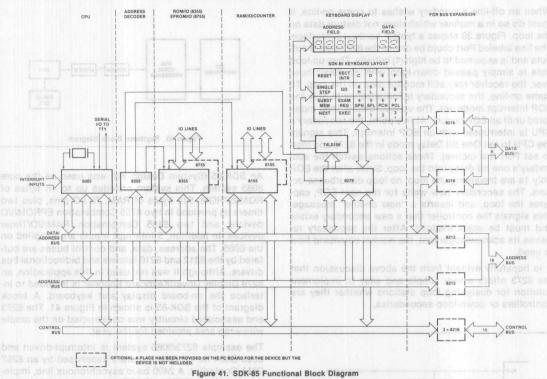

An SDK-85 (System Design Kit) was used as the core 8085 system. This system provides up to 4K bytes of ROM/EPROM, 512 bytes of RAM, 76 I/O pins, plus two timers as provided in two 8755 Combination EPROM/I/O devices and two 8155 Combination RAM/I/O/Timer devices. In addition, 5 interrupt inputs are supplied on the 8085. The address, data, and control buses are buffered by the 8212 and 8216 latches and bidirectional bus drivers. Although it was not used in this application, an 8279 Display Driver/Keyboard Encoder is included to interface the on-board display and keyboard. A block diagram of the SDK-85 is shown in Figure 41. The 8273 and associated circuitry was constructed on the ample wire-wrap area provided for the user.

The example 8273/8085 system is interrupt-driven and uses DMA for all data transfers supervised by an 8257 DMA Controller. A 2400 baud asynchronous line, implemented with an 8251A USART, provides communication between the software and the user. 8253 Programmable Interval Timer is used to supply the baud rate clocks for the 8251A and 8273. (The 8273 baud rate clocks were used only during initial system debug. In actual operation, the modem supplied these clocks via the RS-232 interface.) Two 2142 1K x 4 RAMs provided 512 bytes of transmitter and 512 bytes of receiver buffer memory. (Command and result buffers, plus miscellaneous variables are stored in the 8155s.) The RS-232 interface utilized MC1488 and MC1489 RS-232 drivers and receivers. The schematic of the system is shown in Figure 42.

One detail to note is the DMA and interrupt structure of the transmit and receive channels. In both cases, the receiver is always given the higher priority (8257 DMA channel 0 has priority over the remaining channels and the 8085 RST 7.5 interrupt input has priority over the RST 6.5 input.) Although the choice is arbitrary, this technique minimizes the chance that received data could be lost due to other processor or DMA commitments.

Also note that only one 8205 Decoder is used for both the peripherals' and the memorys' Chip Selects. This was done to eliminate separate memory and I/O decoders since it was known beforehand that neither address space would be completely filled.

The 4 MHz crystal and 8224 Clock Generator were used only to verify that the 8273 operates correctly at that maximum spec speed. In a normal system, the 3.072 MHz clock from the 8085 would be sufficient. (This fact was verified during initial checkout.)

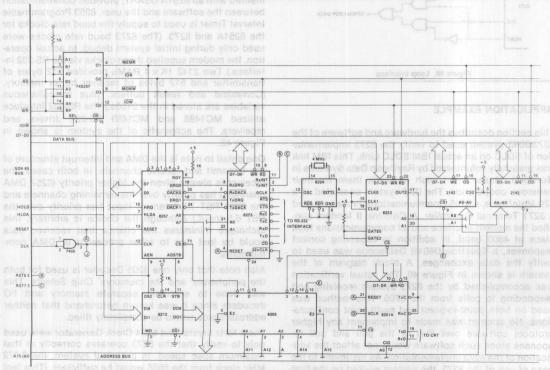

Figure 42. 8273/SDK-85 System

The software consists of the normal monitor program supplied with the SDK-85 and a program to input commands to the 8273 and to display results. The SDK-85 monitor allows the user to read and write on-board RAM, start execution at any memory location, to single-step through a program, and to examine any of the 8085's internal registers. The monitor drives either the on-board keyboard/LED display or a serial TTY interface. This monitor was modified slightly in order to use the 8251A with a 2400 baud CRT as opposed to the 110 baud normally used. The 8273 program implements monitor-like user interface. 8273 commands are entered by a twocharacter code followed by any parameters required by that command. When 8273 interrupts occur, the source of the interrupt is displayed along with any results associated with it. To gain a flavor of how the user/program interface operates, a sample output is shown in Figure 43. The 8273 program prompt character is a "-" and user inputs are underlined.

The "SO 05" implements the Set Operating Mode command with a parameter of 05H. This sets the Buffer and Flag Stream modes. "SS 01" sets the 8273 in NRZI mode using the Set Serial I/O Mode command. The next command specifies General Receiver with a receiver buffer size of 0100H bytes ( $B_0 = 00, B_1 = 01$ ). The "TF" command causes the 8273 to transmit a frame containing an address field of C2H and control field of 11H. The information field is 001122. The "TF" command has a special format. The  $L_0$  and  $L_1$  parameters are computed from the number of information field bytes entered.

After the TF command is entered, the 8273 transmits the frame (assuming that the modem protocol is observed). After the closing flag, the 8273 interrupts the 8085. The 8085 reads the interrupt results and places them in a buffer. The software examines this buffer for new results and if new results exist, the source of the interrupt is displayed along with the results.

In this example, the 0DH result indicates a Frame Complete interrupt. There is only one result for a transmitter interrupt, the interrupt's trailing zero results were included to simplify programming.

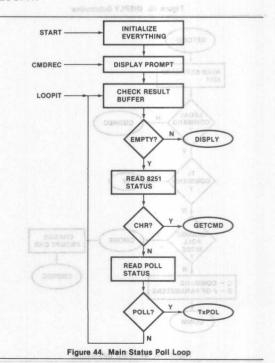

The next event is a frame reception. The interrupt results are displayed in the order read from the 8273. The E0H indicates a General Receive interrupt with the last byte of the information field received on an 8-bit boundary. The 03 00 (R<sub>0</sub>, R<sub>1</sub>) results show that there are 3H bytes of information field received. The remaining two results indicate that the received frame had a C2H address field and a 34H control field. The 3 bytes of information field are displayed on the next line.

Figure 43. Sample 8273 Monitor I/O

Figures 44 through 51 show the flowcharts used for the 8273 program development. The actual program listing is included as Appendix A. Figure 44 is the main status poll loop. After all devices are initialized and a prompt character displayed, a loop is entered at LOOPIT. This loop checks for a change of status in the result buffer of a keyboard character has been received by the 8251 or if a poll frame has been received. If any of these conditions are met, the program branches to the appropriate routine. Otherwise, the loop is traversed again.

The result buffer is implemented as a 255-byte circular buffer with two pointers: CNADR and LDADR. CNADR is the console pointer. It points to the next result to be displayed LDADR is the load pointer. It points to the next empty position in the buffer into which the interrupt handler places the next result. The same buffer is used for both transmitter and receiver results. LOOPIT examines these pointers to detect when CNADR is not equal to LDADR indicating that the buffer contains results which have not been displayed. When this occurs, the program branches to the DISPLY routine.

DISPLY determines the source of the undisplayed results by testing the first result. This first result is necessarily the interrupt result code. If this result is OCH or greater, the result is from a transmitter interrupt. Otherwise it is from a receiver source. The source of the result code is then displayed on the console along with the next four results from the buffer. If the source was a transmitter interrupt, the routine merely repoints the pointer CNADR and returns to LOOPIT. For a receiver source, the receiver data buffer is displayed in addition to the receiver interrupt results before returning to LOOPIT.

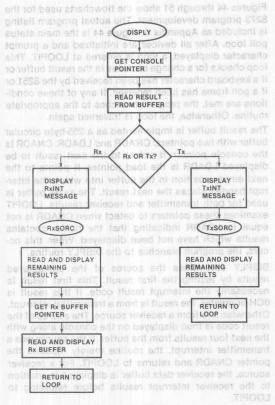

Figure 45. DISPLY Subroutine

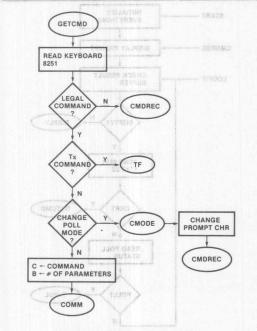

Figure 46. GETCMD Subroutine

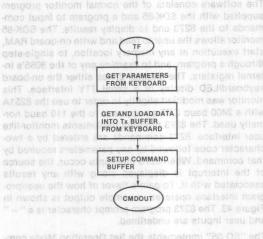

Figure 47. TF Subroutine

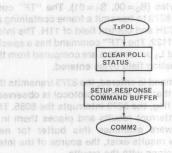

Figure 48. TxPOL Subroutine

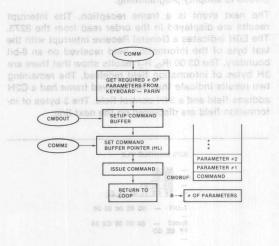

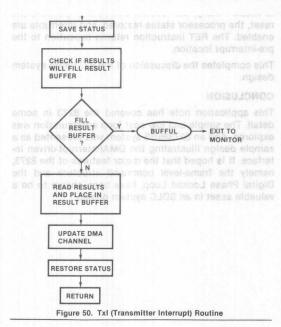

Figure 49. COMM Subroutine with Command Buffer Format

If the result buffer pointers indicate an empty buffer, the 8251A is polled for a keyboard character. If the 8251 has a character, GETCMD is called. There the character is read and checked if legal. Illegal characters simply cause a reprompt. Legal characters indicate the start of a command input. Most commands are organized as two characters signifying the command action; i.e., GR — General Receive. The software recognizes the two character command code and takes the appropriate action. For non-Transmit type commands, the hex equivalent of the command is placed in the C register and the number of parameters associated with that command is placed in the B register. The program then branches to the COMM routine.

The COMM routine builds the command buffer by reading the required number of parameters from the keyboard and placing them at the buffer pointed at by CMDBUF. The routine at COMM2 then issues this command buffer to the 8273.

If a Transmit type command is specified, the command buffer is set up similarly to the the COMM routine; however, since the information field data is entered from the keyboard, an intermediate routine, TF, is called. TF loads the transmit data buffer pointed at by TxBUF. It counts the number of data bytes entered and loads this number into the command buffer as  $L_0$ ,  $L_1$ . The command is then issued to the 8273 by jumping to CMDOUT.

One command does not directly result in a command being issued to the 8273. This command, Z, operates a software flip-flop which selects whether the software will respond automatically to received polling frames. If

memory location POLIN is made nonzero by the receiver interrupt handler. LOOPIT examines this location and if it is nonzero, causes a branch to the TxPOL routine. The TxPOL routine clears POLIN, sets a pointer to a special command buffer at CMDBUF1, and issues the command by way of the COMM2 entry in the COMM routine. The special command buffer contains the appropriate response frame for the poll frame received. These actions only occur when the Z command has changed the prompt to a '+'. If the prompt is normal '-', polling frames are displayed as normal frames and no response is transmitted. The Poll-Response mode was used during the IBM tests.

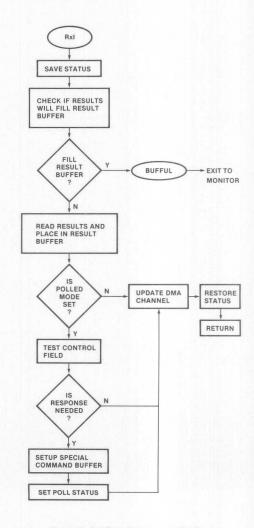

Figure 51. RxI (Recevier Interrupt) Routine

The final two software routines are the transmitter and receiver interrupt handlers. The transmit interrupt handler, TxI, simply saves the registers on the stack and checks if loading the result buffer will fill it. If the result buffer will overfill, the program is exited and control is passed to the SDK-85 monitor. If not, the results are read from the TxI/R register and placed in the result buffer at LDADR. The DMA pointers are then reset, the registers restored, and interrupts enabled. Execution then returns to the pre-interrupt location.

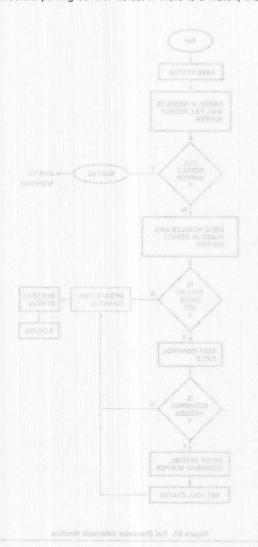

The receiver interrupt handler, RxI, is only slightly more complex. As in TxI, the registers are saved and the possibility of overfilling the result buffer is examined. If the result buffer is not full, the results are read from RxI/R and placed in the buffer. At this point the prompt character is examined to see if the Poll-Response mode is selected. If so, the control field is compared with two possible polling control fields. If there is a match, the

special command buffer is loaded and the poll indicator, POLIN, is made nonzero. If no match occurred, no action is taken. Finally, the receiver DMA buffer pointers are reset, the processor status restored, and interrupts are enabled. The RET instruction returns execution to the pre-interrupt location.

This completes the discussion of the 8273/8085 system design.

### CONCLUSION

This application note has covered the 8273 in some detail. The simple and low cost loop configuration was explored. And an 8273/8085 system was presented as a sample design illustrating the DMA/interrupt-driven interface. It is hoped that the major features of the 8273, namely the frame-level command structure and the Digital Phase Locked Loop, have been shown to be a valuable asset in an SDLC system design.

# bit characters noitsuborini for ASCII data, and eight-bit characters and eight-bit characters.

The 8274 Multi-protocol serial controller (MPSC) is a sophisticated dual-channel communications controller that interfaces microprocessor systems to high-speed serial data links (at speeds to 880K bits per second) using synchronous or asynchronous protocols. The 8274 interfaces easily to most common microprocessors (e.g., 8048, 8051, 8085, 8086, amd 8088), to DMA controllers such as the 8237 and 8257, and to the 8089 I/O processor. Both MPSC communication channels are completely independent and can operate in a full-duplex communication mode (simultaneous data transmission and reception.

Communication Functions

The 8274 performs many communications oriented functions, including:

Converting data bytes from a microprocessor system into a serial bit stream for transmission over the data link to a receiving system.

Receiving serial bit streams and reconverting the data into parallel data bytes that can easily be processed by the microprocessor system.

Performing error checking during data transfers. Error checking functions include computing/transmitting error codes (such as parity bits or CRC bytes) and using these codes to check the validity of received data.

Operating independently of the system processor in a manner designed to reduce the system overhead involved in data transfers.

System Interface Transit of TRATE ventions not

The MPSC system interface is extremely flexible, supporting the following data transfer modes:

1. Polled Mode. The system processor periodically reads (polls) an 8274 status register to determine when a

character has been received, when a character is needed for transmission, and when transmission errors are detected.

- 2. Interrupt Mode. The MPSC interrupts the system processor when a character has been received, when a character is needed for transmission, and when transmission errors are detected.
- 3. DMA Mode. The MPSC automatically requests data transfers from system memory for both transmit and receive functions by means of two DMA request signals per serial channel. These DMA request signals may be directly interfaced to an 8237 or 8257 DMA controller or to an 8089 1/0 processor.
- 4. WAIT Mode. The MPSC ready signal is used to synchronize processor data transfers by forcing the processor to enter wait states until the 8274 is ready for another data byte. This feature enables the 8274 to interface directly to an 8086 or 8088 processor by means of string I/O instructions for very high speed data links.

#### Normally the data link is in an idle or equal

This application note describes the use of the 8274 in asynchronous communication modes. Asynchronous communication is typically used to transfer data to/from video display terminals, modems, printers, and other low-to-medium speed peripheral devices. Use of the 8274 in both interrupt driven and polled system environments is described. Use of the DMA and WAIT modes are not described since these modes are employed mainly in synchronous communication systems where extremely high data rates are common. Programming examples are written in PL/M--86 (Appendix B and Appendix C). PL/M-86 is executed by the iAPX-86 and iAPX-88 processor families. In addition, PL/M-86 is very similar to PL/M-80 10 518 10 911 (executed by the MCS-80 and MCS-85 processor families). In addition, Appendix D describes a simple application example using an SDK-86 in an iAPX-86/88 environments delias y fementa at anotasimament

#### 2. Serial Asynchronous Data Links Characters

A serial asynchronous interface is a method and In asynchronous mode characters may vary in of data transmission in which the receiving and transmitting systems need not be synchronized. Instead of transmitting clocking information with the data, locally generated clocks (16, 32 or 64 times as fast as the data transmission rate) are used by the transmitting and receiving systems. When a character of information is sent by the transmitting system, the character data is framed (preceded and followed) by special START and STOP bits. This framing information permits the receiving system to temporarily synchronize with the data transmission. (Refer to Figure 1 during the following discussion of asynchronous data transmission.)

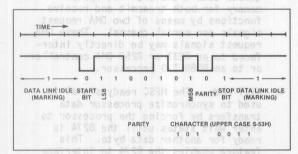

Figure 1. Transmission of a 7-Bit ASCII Character with Even of a Parity untann OVI putate to ansem you

Normally the data link is in an idle or marking state, continuously transmitting a "mark" (binary 1). When a character is to be sent, the character data bits are immediately preceded by a "space" (binary 0 START bit). The mark-to-space transition informs the receiving system that a character of information will immediately follow the start bit. Figure 1 illustrates the transmission of a 7-bit ASCII character (upper case S) with even parity. Note that the character is transmitted immediately following the start bit. Data bits within the character are transmitted from leastsignificant to most-significant. The parity bit is transmitted immediately following the character data bits and the STOP framing bit (binary 1) signifies the end of the character.

Asynchronous interfaces are often used with human interface devices such as CRT/keyboard units where the time between data transmissions is extremely variable.

length from five to eight bits. The character length depends on the coding method used. For example, five-bit characters are used when transmitting Baudot Code, sevenbit characters are required for ASCII data, and eight-bit characters are needed for EBCDIC and binary data. To transmit messages composed of multiple characters, each character is framed and transmitted separately (Figure 2).

This framing method ensures that the receiving system can easily synchronize with the start and stop bits of each character, preventing receiver synchronization errors. In addition, this synchronization method makes both transmitting and receiving systems insensitive to possible time delays between character transmissions.

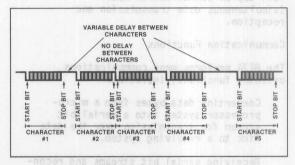

Figure 2. Multiple Character Transmission

#### Framing

Character framing is accomplished by the START and STOP bits described previously. When the START bit transition (mark to space) is detected, the receiving system assumes that a character of data will follow. In order to test this assumption (and isolate noise pulses on the data link), the receiving system waits one-half bit time and samples the data link again. If the link has returned to the marking state, noise is assumed, and the receiver waits for another START bit transition.

When a valid START bit is detected, the receiver samples the data link for each bit of the following character. Character data bits and the parity bit (if required) are sampled at their nominal centers until all required characters are received. Immediately following the data bits, the receiver samples the data link for the STOP bit, indicating the end of the character. Most systems permit specification of 1, 1 1/2, or 2 stop bits.

Floure 3 filustrates typical MPSC con-

## figurations for use with an 8088 micro- gnimit

The transmitter and receiver in an asynchronous data link arrangement are clocked independently. Normally, each clock is generated locally and the clocks are not synchronized. In fact, each clock may be a slightly different frequency. (In practice. the frequency difference should not exceed a few percent. If the transmitter and receiver clock rates vary substantially, errors will occur because data bits may be incorrectly identified as START or STOP framing bits.) These clocks are designed to operate at 16, 32, or 64 times the communications data rate. These clock speeds allow the receiving device to correctly sample the incoming bit stream.

Serial interface data rates are measured in bits/second. The term baud is used to specify the number of times per second that the transmitted signal level can change states. In general, the baud is not equal to the bit rate. Only when the transmitted signal has two states (electrical levels) is the baud rate equal to the bit rate.

Most point-to-point serial data links use RS-232-C, RS-422, or RS-423 electrical interfaces. These specifications call for two electrical signal levels (the baud is equal to the bit rate). Modem interfaces, however, may often have differing bit and baud rates.

While there are generally no limitations on the data transmission rates used in an asynchronous data link, a limited set of rates has been standardized to promote equipment interconnection. These rates vary from 75 bits per second to 38,400 bits per second. Table 1 illustrates typical

Table 1. Communication Data Rates and Associated Transmitter/Receiver Clock Rates

Data Rate (bits/second)	CI	ock Rate (k	Hz)

asynchronous data rates and the associated clock frequencies required for the transmitter and receiver circuits.

## I/O channel responds to two I/O or memory addresses as shown in Table 2. In additiviting

In order to detect transmission errors, and and parity bit may be added to the character data as it is transferred over the data link. The parity bit is set or cleared to make the total number of "one" bits in the character even (even parity) or odd (odd parity). For example, the letter "A" is represented by the seven-bit ASCII code 1000001 (41H). The transmitted data code (with parity) for this character contains eight bits: 01000001 (41H) for even parity and 11000001 (OC1H) for odd parity. Note that a single bit error changes the parity of the received character and is therefore easily detected. The 8274 supports both odd and even parity checking as well as a parity disable mode to support binary data transfers.

#### Communication Modes

Serial data transmission between two devices can occur in one of three modes. In the simplex transmission mode, a data link can transmit data in one direction only. In the half-duplex mode, the data link can transmit data in both directions, but not simultaneously. In the full-duplex mode (the most common), the data link can transmit data in both directions simultaneously. The 8274 directly supports the full-duplex mode and will interface to simplex and half-duplex communication data links with appropriate software controls.

#### Break Condition

Asynchronous data links often include a special sequence known as a break condition. A break condition is initiated when the transmitting device forces the data link to a spacing state (binary 0) for an extended length of time (typically 150 milliseconds). Many terminals contain keys to initiate a break sequence. Under software control, the 8274 can initiate a break sequence when receiving data.

## 3. MPSC System Interface

Hardware Environment wards reviewed bas restrict

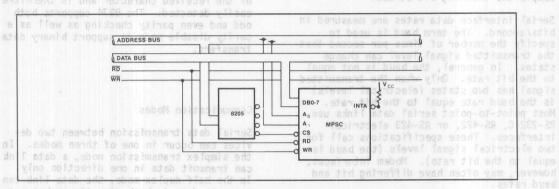

The 8274 MPSC interfaces to the system processor over an 8-bit data bus. Each serial I/O channel responds to two I/O or memory addresses as shown in Table 2. In addition, and the MPSC supports vectored and daisychained interrupts.

Table 2: 8274 Addressing. The 8274 may be configured for memory mapped or I/O mapped operation.

cs	A	A <sub>0</sub>	Read Operation	Write Operation
0	0	0	Ch. A Data Read	Ch. A Data Write
0	1	0	Ch. A Status Read	Ch. A Command/Parameter
0	201	0.00	Ch. B Data Read	Ch. B Data Write
0	1 1	1	Ch. B Status Read	Ch. B Command/Parameter
1	X	X	High Impedence	High Impedence

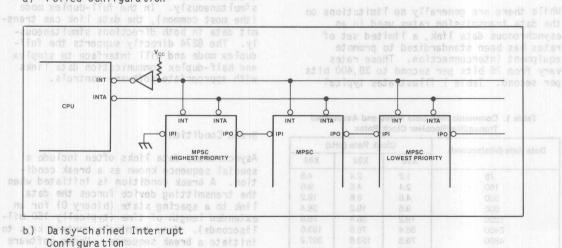

The 8274/processor hardware interface can be configured in a flexible manner, depending on the operating mode selected --polled, interrupt driven, DMA, or WAIT. Figure 3 illustrates typical MPSC configurations for use with an 8088 microprocessor in the polled and interrupt driven modes.

All serial-to-parallel conversion, parallel-to-serial conversion, and parity checking required during asynchronous serial I/O operation is automatically performed by the MPSC.

#### a) Polled Configuration

control, the 8274 can initiate a break

#30400 but \$3.60 pniss many Figure 3: 8274 Hardware Interface for Polled and Interrupt Driven Environments

Operational Interface

Command, parameter, and status information is stored in 22 registers within the MPSC (8 writable registers and 3 readable registers for each channel). These registers are all accessed by means of the command/status ports for each channel. An internal pointer register selects which of

the command or status registers will be written or read during a command/status access of an MPSC channel. Figure 4 diagrams the command/status register architecture for each serial channel. In the following discussion, the writable registers will be referred to as WRO through WR7 and the readable registers will be referred to as RRO through RR2.

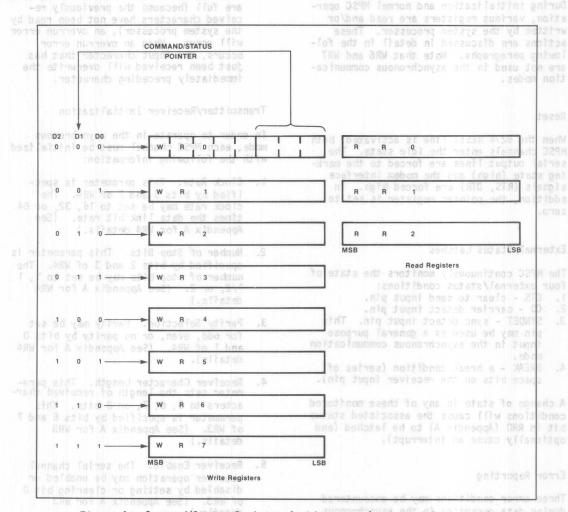

Figure 4: Command/Status Register Architecture (each serial channel)

The least significant three bits of WRO are automatically loaded into the pointer register every time WRO is written. After reset, WRO is set to zero so that the first write to a command register causes the data to be loaded into WRO (thereby setting the pointer register). After WRO is written, the following read or write accesses the

register selected by the pointer. The pointer is reset after the read or write operation is completed. In this manner, reading or writing an arbitrary MPSC channel register requires two I/O accesses. The first access is always a write command. This write command is used to set the pointer register. The second access is

either a read or a write command; the pointer register (previously set) will ensure that the correct internal register is read or written. After this second access, the pointer register is automatically reset. Note that writing WRO and reading RRO does not require presetting of the pointer register.

During initialization and normal MPSC operation, various registers are read and/or written by the system processor. These actions are discussed in detail in the following paragraphs. Note that WR6 and WR7 are not used in the asynchronous communication modes.

#### Reset

When the 8274 RESET line is activated, both MPSC channels enter the idle state. The serial output lines are forced to the marking state (high) and the modem interface signals (RTS, DTR) are forced high. In addition, the pointer register is set to zero.

#### External/Status Latches

The MPSC continuously monitors the state of four external/status conditions:

- CTS clear to send input pin.
- 2. CD carrier detect input pin.
- SYNDET sync detect input pin. This pin may be used as a general purpose input in the asynchronous communication mode.
- BREAK a break condition (series of space bits on the receiver input pin).

A change of state in any of these monitored conditions will cause the associated status bit in RRO (Appendix A) to be latched (and optionally cause an interrupt).

#### Error Reporting

Three error conditions may be encountered during data reception in the asynchronous mode:

1. Parity. If parity bits are computed and transmitted with each character and the MPSC is set to check parity (bit 0 in WR4 is set), a parity error will occur whenever the number of "1" bits within the character (including the parity bit) does not match the odd/even setting of the parity check flag (bit 1 in WR4).

- Framing. A framing error will occur if a stop bit is not detected immediately following the parity bit (if parity checking is enabled) or immediately following the most-significant data bit (if parity checking is not enabled).
- 3. Overrun. If an input character has been assembled but the receiver buffers are full (because the previously received characters have not been read by the system processor), an overrun error will occur. When an overrun error occurs, the input character that has just been received will overwrite the immediately preceding character.

#### Transmitter/Receiver Initialization

In order to operate in the asynchronous mode, each MPSC channel must be initialized with the following information:

- Clock Rate. This parameter is specified by bits 6 and 7 of WR4. The clock rate may be set to 16, 32, or 64 times the data link bit rate. (See Appendix A for WR4 details.)
- Number of Stop Bits. This parameter is specified by bits 2 and 3 of WR4. The number of stop bits may be set to 1, 1 1/2, or 2. (See Appendix A for WR4 details.)
- Parity Selection. Parity may be set for odd, even, or no parity by bits 0 and 1 of WR4. (See Appendix A for WR4 details).
- Receiver Character Length. This parameter sets the length of received characters to 5, 6, 7, or 8 bits. This parameter is specified by bits 6 and 7 of WR3. (See Appendix A for WR3 details.)
- 5. Receiver Enable. The serial channel receiver operation may be enabled or disabled by setting or clearing bit 0 of WR3. (See Appendix A for WR3 details.)
- 6. Transmitter Character Length. This parameter sets the length of transmitted characters to 5, 6, 7, or 8 bits. This parameter is specified by bits 5 and 6 of WR5. (See Appendix A for WR5 details.) Characters of less than 5 bits in length may be transmitted by setting the transmitted length to five bits (set bits 5 and 6 of WR5 to 1).

7. Transmitter Enable. The serial channel transmitter operation may be enabled or disabled by setting or clearing bit 3 of WR5. (See Appendix A for WR5 Channel B Character Available(.sliable

For data transmission via a modem or RS-232-C interface, the following information must also be specified: The formand

- 1. Request to Send/Data Terminal Ready. Must be set to indicate status of data terminal equipment. Request to send is controlled by bit ! of WR5 and data terminal ready is controlled by bit 7. (See Appendix A for WR5 details.)
- 2. Auto Enable. May be set to allow the MPSC to automtically enable the channel transmitter when the clear to send signal is active and to automatically enable the receiver when the carrier detect signal is active. Auto Enable is controlled by bit 5 of WR3. (See Appendix A for WR3 details.)

During initialization, it is desirable to quarantee that the external/status latches reflect the latest interface information. Since up to two state changes are internally stored by the MPSC, at least two Reset External/Status Interrupt commands must be issued. This procedure is most easily accomplished by simply issuing this reset command whenever the pointer register is set during initialization. at dourselet

Figure 5. Sample 8274 initialization procedure for polled officeration, no decembed at partiages application. For example, the receiv-

Polled Operation and and to notestmens of the

In the polled mode, the processor must monitor the MPSC status by testing the appropriate bits in the read register. Data available, status, and error conditions are represented in RRO and RR1 for channels A and B. An example of MPSC polled transmitter/receiver routines are given in Appendix B. The following routines are detailed: of betrogen ers anditaredd to teber

1. MPSC\$POLL\$RCV\$CHARACTER - This procedure receives a character from the serial data link. The routine waits until the character available flag in RRO has been set. When this flag indicates that a character is available, RRI is checked for errors (overrun, parity, or framing). If an error is detected, the character in the MPSC receive buffer must be read and discarded and the error routine (RECEIVESERROR) is called. If no receive errors have been detected, the character is input from the 8274 data port and returned to the calling program.

MPSC\$POLL\$RCV\$CHARACTER requires three parameters - the address of the 8274 channel data port (data\$port), the address of the 8274 channel command port (cmd\$port), and the address of a byte variable in which to store the received character (character\$ptr).

AFN: 01995A

- 2. MPSC\$POLL\$TRAN\$CHARACTER This procedure transmits a character to the serial data link. The routine waits until the transmitter buffer empty flag has been set in RRO before writing the character to the 8274.

  MPSC\$POLL\$TRAN\$CHARACTER requires three parameters the address of the 8274 channel data port (data\$port), the address of the 8274 channel command port (cmd\$port), and the character of data that is to be transmitted (character).
- 3. RECEIVE\$ERROR This procedure processes receiver errors. First, an Error Reset command is written to the affected channel. All additional error processing is dependent on the specific application. For example, the receiving device may immediately request retransmission of the character or wait until a message has been completed. RECEIVE\$ERROR requires two parameters the address of the affected 8274 command port (cmd\$port) and the error status (status) from 8274 register RR1.

#### Interrupt Driven Operation signske nA .8 bas

In an interrupt driven environment, all based receiver operations are reported to the system processor by means of interrupts. Once a character has been received and assembled, the MPSC interrupts the system processor. The system processor must then read the character from the MPSC data buffer and clear the current interrupt. During transmission, the system processor starts serial I/O by writing the first character of a message to the MPSC. The MPSC interrupts the system processor whenever the next character is required (i.e., when the transmitter buffer is empty) and the processor responds by writing the next character of the message to the MPSC data port for the appropriate channel. ASS and

By using interrupt driven I/O, the MPSC proceeds independently of the system processor, signalling the processor only when characters are required for transmission, when characters are received from the data link, or when errors occur. In this manner, the system processor may continue execution of other tasks while serial I/O is performed concurrently.

#### Interrupt Configurations

The 8274 is designed to interface to 8085and 8086-type processors in much the same manner as the 8259A is designed. When operating in the 8085 mode, the 8274 causes a "call" to a prespecified interrupt service routine location. In the 8086 mode, the 8274 presents the processor with a one-byte interrupt type number. This interrupt type number is used to "vector" through the 8086 interrupt service table. In either case, the interrupt service address or interrupt type number is specified during MPSC initialization.

To shorten interrupt latency, the 8274 can be programmed to modify the prespecified interrupt vector so that no software overhead is required to determine the cause of an interrupt. When this "status affects vector" mode is enabled, the following eight interrupts are differentiated automatically by the 8274 hardware:

- 1. Channel B Transmitter Buffer Empty
- 2. Channel B External/Status Transition
- 3. Channel B Character Available
- 4. Channel B Receive Error as many sist and
- 5. Channel A Transmitter Buffer Empty
- 6. Channel A External/Status Transition
- 7. Channel A Character Available
- 8. Channel A Receive Error ypsey fantmas

#### Interrupt Sources/Priorities

The 8274 has three interrupt sources for each channel:

- 1. Receiver (RxA, RxB). An interrupt is initiated when a character is available in the receiver buffer or when a receiver error (parity, framing, or overrun) is detected.
- 2. Transmitter (TxA, TxB). An interrupt is initiated when the transmitter buffer is empty and the 8274 is ready to accept another character for transmission.
- External/Status (ExTA, ExTB). An interrupt is initiated when one of the external/status conditions (CD, CTS, SYNDET, BREAK) changes state.

The 8274 supports two interrupt priority orderings (selectable during MPSC initialization) as detailed in Appendix A, WR2, CH-A.

Interrupt Initialization A RAHDE BY I BORRES SAM ...

In addition to the initialization parameters required for polled operation, the following parameters must be supplied to the 8274 to specify interrupt operation:

- Transmit Interrupt Enable. Transmitter buffer empty interrupts are separately enabled by bit 1 of WR1. (See Appendix A for WR1 details.)
- 2. Receive Interrupt Enable. Receiver interrupts are separately enabled in one of three modes: a) interrupt on first received character only and on receive errors (used for message oriented transmission systems), b) interrupt on all received characters and on receive errors, but do not interrupt on parity errors, and c) interrupt on all received characters and on receive errors (including parity errors). The ability to separately disable parity interrupts can be extremely useful when transmitting messages. Since the parity error bit in RR1 is latched, it will not be reset until an error reset operation is performed. Therefore, the parity error bit will be set if any parity errors were detected in a multi-character message. If this mode is used, the serial I/O software must poll the parity error bit at the completion of a message and issue an error reset if appropriate. The receiver interrupt mode is controlled by bits 3 and 4 of WR1. (See Appendix A for WR1 details.)
- External/Status Interrupts. External/Status interrupts can be separately enabled by bit 0 of WR!. (See Appendix A for WR! details.)
- Interrupt Vector. An eight-bit interrupt service routine location (8085) or interrupt type (8086) is specified through WR2 of channel B. (See Appendix A for WR2 details). Table 3 lists interrupt vector addresses generated by the 8274 in the "status affects vector" mode.
- Status Affects Vector Mode. The 8274 will automatically modify the interrupt vector if bit 3 of WRl is set. (See Appendix A for WRl details.)

- 6. System Configuration. Specifies the 8274 data transfer mode. Three configuration modes are available: a) interrupt driven operation for both channels, b) DMA operation for both channels, and c) DMA operation for channel A, interrupt driven operation for channel B. The system configuration is specified by means of bits 0 and 1 of WR2 (channel A). (See Appendix A for WR2 details).
- Interrupt Priorities. The 8274 permits software specification of receive/ transmit priorities by means of bit 2 of WR2 (channel A). (See Appendix A for WR2 details.)
- 8. Interrupt Mode. Specifies whether the MPSC is to operate in a non-vectored mode (for use with an external interrupt controller), in an 8086 vectored mode, or in an 8085 vectored mode. This parameter is specified through bits 3 and 4 of WR2 (channel A). (See Appendix A for WR2 details.)

An MPSC interrupt initialization procedure (MPSC\$INT\$INIT) is listed in Appendix C.

Interrupt Service Routines and meday

Appendix C lists four interrupt service procedures, a buffer transmission procedure, and a buffer reception procedure that illustrate the use of the 8274 in interrupt driven environments. Use of these procedures assumes that the 8086/8088 interrupt vector is set to 20H and that channel B is used with the "status affects vector" mode enabled.

- 1. TRANSMIT\$BUFFER This procedure begins serial transmission of a data buffer. Two parameters are required a pointer to the buffer (buf\$ptr) and the length of the buffer (buf\$length). The procedure first sets the global buffer pointer, buffer length, and initial index for the transmitter interrupt service routine and initiates transmission by writing the first character of the buffer to the 8274. The procedure then enters a wait loop until the I/O completion status is set by the transmit interrupt service routine (MPSC\$TRANSMIT\$CHARACTER\$INT).
- 2. RECEIVESBUFFER This procedure inputs a line (terminated by a line feed) from a serial I/O port. Two parameters are required - a pointer to the input buffer (buf\$ptr) and a pointer to the buffer length variable (buf\$length\$ptr). The buffer length will be set by this procedure when the complete line has been input. The procedure first sets the global buffer pointer and initial index for the receiver interrupt service routine. RECEIVE\$BUFFER then enters a wait loop until the I/O completion status is set by the receive interrupt routine (MPSC\$RECEIVE\$CHAR-ACTERSINT).

- 3. MPSC\$RECEIVE\$CHARACTER\$INT This procedure is executed when the MPSC Tx buffer empty interrupt is acknowledged. If the current transmit buffer index is less than the buffer length, the next character in the buffer is written to the MPSC data port and the buffer pointer is updated. Otherwise the transmission complete status is posted.
- 4. MPSC\$RECEIVE\$CHARACTER\$INT This procedure is executed when a character has been assembled by the MPSC and the MPSC has issued a character available interrupt. If no input buffer has been set up by RECEIVE\$BUFFER, the character is ignored. If a buffer has been set up, but it is full, a receive overrun error is posted. Otherwise, the received character is read from the MPSC data port and the buffer index is updated. Finally, if the received character is a line feed, the reception complete status is posted.
- 5. RECEIVESERRORSINT This procedure is executed when a receive error is detected. First, the error conditions are read from RR1 and the character currently in the MPSC receive buffer is read and discarded. Next, an Error Reset command is written to the affected channel. All additional error procession is application dependent.
- 6. EXTERNAL\$STATUS\$CHANGE\$INT This procedure is executed when an external status condition change is detected. The status conditions are read from RRO and a Reset External/Status Interrupt command is issued. Further error processing is application dependent.

Appendix A for WRI details.)

4. Data Link Interface

Serial Data Interface as mi beau for I brammo 3

Each serial I/O channel within the 8274

MPSC interfaces to two data link lines -one line for transmitting data and one for
receiving data. During transmission, characters are converted from parallel data
format (as supplied by the system processor
or DMA device) into a serial bit stream
(with START and STOP bits) and clocked out
on the TxD pin. During reception, a serial
bit stream is input on the RxD pin, framing
bits are stripped out of the data stream,
and the resulting character is converted to
parallel data format and passed to the system processor or DMA device.

Data Clocking

As discussed previously, the frequency of data transmission/reception on the data link is controlled by the MPSC clock in conjunction with the programmed clock divider (in register WR4). The 8274 is designed to permit all four serial interface lines (TxD and RxD for each channel) to operate at different data rates. Four clock input pins (TxC and RxC for each channel) are available for this function. Note that the clock rate divider specified in WR4 is used for both RxC and TxC on the appropriate channel are independent.

data when the transmit forthood meboM

The following four modem interface signals may be connected to the 8274:

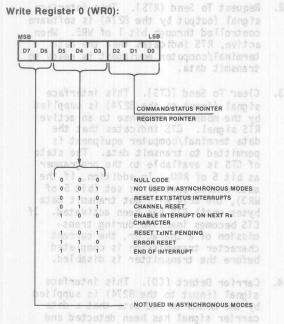

1. Data Terminal Ready (DTR). This interface signal (output by the 8274) is software controlled through bit 7 of WR5. When active, DTR indicates that the data terminal/computer equipment is active and ready to interact with the data communications channel. In addition, this signal prepares the modem for connection to the communication

channel and maintains connections previously established (e.g., manual call origination).

- Request To Send (RTS). This interface signal (output by the 8274) is software controlled through bit 1 of WR5. When active, RTS indicates that the data terminal/computer equipment is ready to transmit data.
- 3. Clear To Send (CTS). This interface signal (input to the 8274) is supplied by the modem in response to an active RTS signal. CTS indicates that the data terminal/computer equipment is permitted to transmit data. The state of CTS is available to the programmer as bit 5 of RRO. In addition, if the auto enable control is set (bit 5 of WR3), the 8274 will not transmit data bytes until RTS has been activated. If CTS becomes inactive during transmission of a character, the current character transmission is completed before the transmitter is disabled.
- 4. Carrier Detect (CD). This interface signal (input to the 8274) is supplied by the modem to indicate that a data carrier signal has been detected and that a valid data signal is present on the RxD line. The state of CD is available to the programmer as bit 3 of RRO. In addition, if the auto enable control is set (bit 5 of WR3), the 8274 will not enable the serial receiver until CD has been activated. If the CD signal becomes inactive during reception of a character, the receiver is disabled, and the partially received character is lost.

In addition to the above modem interface signals, the 8274 SYNDET input pin for channel A may be used as a general purpose input in the asynchronous communication mode. The status of this signal is available to the programmer as bit 4 of status register RRO.

Appendix A: Command/Status Details for Asynchronous Communication

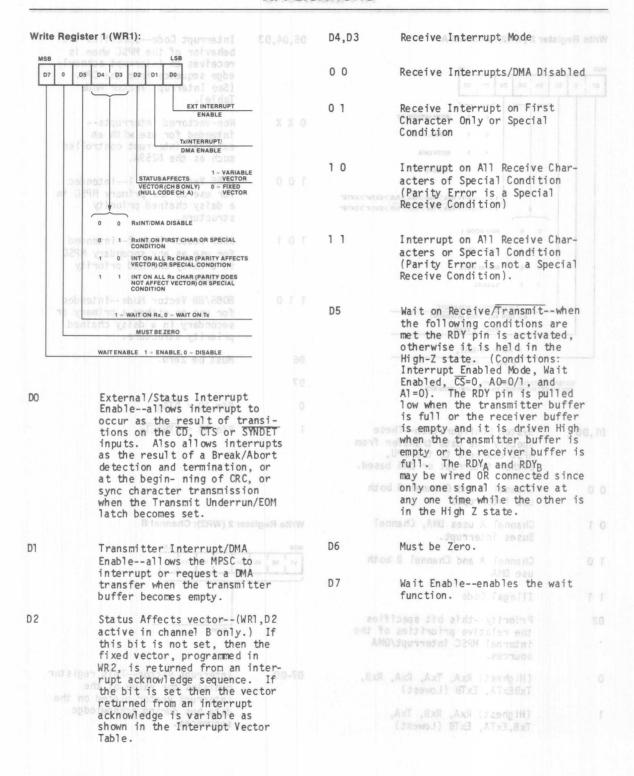

- D2, D1, D0 Command/Status Register Pointer bits determine which writeregister the next byte is to be do and written into, or which read-inu register the next byte is to be read from. After reset, the first byte written into either channel goes into WRO. Following a read or write to any register (except WRO) the pointer will point to WRO.
- D5,D4,D3 Command bits determine which of the basic seven commands are to be performed. register RRO.

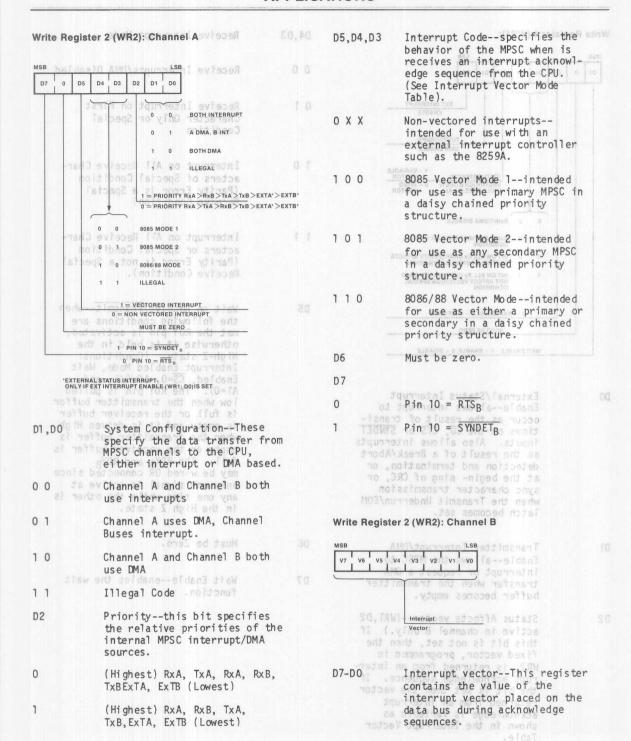

channel A may be used as a general purpose

- Command O Null--has no effect.
- Command 1 Not used in asynchronous modes.
- Command 2 Reset External/Status Inter--- rupts--resets the latched status bits of RRO and re-enables them, allowing sinterrupts to occur again.
- Command 3 Channel Reset--resets the Latched Status bits of RRO, the Targe interrupt prioritization logic and all control registers for the channel. Four extra system clock cycles should be allowed for MPSC reset time before any additional commands or controls are written into the channel.
- Command 4 Enable Interrupt on Next Receive Character--if the Interrupt on First Receive Character mode is selected, this command reactivates that mode after each complete message is received to prepare the MPSC for the next message.
- Command 5 Reset Transmitter Interrupt Pending--if The Transmit state of the state Interrupt mode is selected, the MPSC automatically interrupts data when the transmit buffer about becomes empty. When there are no more characters to be sent, issuing this command prevents further transmitter interrupts until the next character has been completely sent.

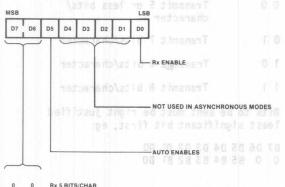

saftware controlled through bit 7 of

- Command 6 Error Reset--error latches, Parity and Overrun errors in - tobs nRR1 are reset and fact nummos at ab
- Command 7 End of Interrupt -- resets the interrupt-in-service latch of the highest-priority internal device under service.
